FOR PROSPECTUS OF THE MEDICAL NEWS, SEE LAST PAGE OF COVER.

Special Notice: Subscribers to either **The Medical News** or **The American Journal of the Medical Sciences,** who remit for their subscriptions thereto for the coming year, before February 1st, 1884, will receive, free of postage, covers for their respective periodicals upon the completion of the volumes.

SECTION V.—JUST READY.

A SYSTEM OF HUMAN ANATOMY.

By Harrison Allen, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

To be complete in Six Sections, comprising over 700 quarto pages of letter-press, with 109 full-page lithographic plates, containing 380 figures, and about 150 wood-engravings.

Each Section in an individual portfolio. Price per Section, $3.50.

SECTION V, **Nervous System,** contains 129 pages of text, 14 full-page plates and 35 woodcuts. *Just ready.* SECTION VI, **Organs of Sense, of Digestion and Genito-Urinary Organs.** *In press.*

The present number is equal in style and execution to those which preceded it. In detail exhaustive, in diction concise and clear, in illustration marvellous, it is destined to take rank among the world's great scientific works.—*Louisville Medical News,* December 29, 1883.

STUDENTS' SERIES OF MANUALS.

The additional volumes are just ready.

THE DISSECTOR'S MANUAL.

By W. B. Clarke, F.R.C.S., and C. B. Lockwood, F.R.C.S.,

DEMONSTRATORS OF ANATOMY AT ST. BARTHOLOMEW'S HOSPITAL MEDICAL SCHOOL, LONDON.

In one pocket-size 12mo. volume of 396 pages, with 49 illustrations. Cloth, $1.50.

HUMAN PHYSIOLOGY.

By Henry Power, M.B., F.R.C.S.

EXAMINER IN PHYSIOLOGY, ROYAL COLLEGE OF SURGEONS OF ENGLAND.

In one pocket-size 12mo. volume of 396 pages, with 47 illustrations. Cloth, $1.50.

HENRY C. LEA'S SON & CO., PHILADELPHIA.

PRIVATE TREATMENT OF OPIUM HABITUÉS

DR. J. B. MATTISON

Continues to receive cases of Opium Habituation at his residence, **185 Livingston St. Brooklyn, N. Y.**, to whom he devotes his special professional attention. Number limited—four—and select. None but opium habitués admitted. Advantages: handsomely furnished apartments, desirable privacy, a liberal cuisine, cheerful social surroundings, and personal professional attention based upon several years' experience in the management of this disease. Details on application.

Successor to DR. D. BLY,
ROCHESTER, N. Y.

MENTAL AND NERVOUS CASES,

Among the best class of private patients, may secure in the residence of a physician the desirable privacy, special personal attention and most comfortable accommodations, and, at the same time, have the advantage of experienced medical care and treatment. The location is in the beautiful hill-country of Delaware County, eighteen miles from Philadelphia. The house is exceedingly light and cheerful. The grounds comprise fifteen acres; are high and picturesquely situated. The region is as healthful as can be found in Pennsylvania. Physician has had ten years' extensive experience in this department of medicine. Number of cases limited to six.

P. O. AND TELEGRAPH ADDRESS:

DR. ALFRED T. LIVINGSTON,
WAWA, DEL. CO., PA.

THE LONDON MEDICAL TIMES AND GAZETTE.

32 PAGES WEEKLY FOR $4.00 PER ANNUM, POST FREE.

Commencing with the number for January 5th, 1884, the London "Medical Times and Gazette" will undergo an *alteration in the size of page*, that will make it much more convenient for handling and binding. A *clearer type*, better accommodated to the eye, will be employed, an *increase in the number of pages* will be made, thus increasing the amount of reading matter. The *contents* will be printed on the first page of reading matter, enabling them to be bound up with the volume, and a *reduction in the price, of one-half*, will make it at once one of the cheapest and best Weekly Medical Papers now published.

SUBSCRIPTION PRICE FOR 1884, **$4.00**, POST FREE.

CLUB RATES:

The London Medical Times and Gazette (Weekly)	$4.00		
The Polyclinic (Monthly)	1.00	Together for 1884,	$7.00
*The Ophthalmic Review (Monthly)	3.00		
The London Medical Times and Gazette	4.00	" "	4.50
The Polyclinic	1.00		
The London Medical Times and Gazette	4.00	" "	6.50
The Ophthalmic Review	3.00		

**The Ophthalmic Review* is a Monthly Record of Ophthalmic Science, with illustrations; published in London. Edited by KARL GROSSMAN, PRIESTLEY SMITH and JOHN R. STORY. Sample numbers of these Journals sent upon application.

NEARLY READY.

THE MEDICAL REGISTER AND DIRECTORY, OF PHILADELPHIA

Containing the names, office hours, addresses, date of graduation, etc., of all Physicians and Surgeons of every school in Philadelphia County, classified under their respective schools, Regular, Homœopathic and Electic; those practising without diplomas and those who have graduated from the Penn Medical College and from the Philadelphia University of Medicine and Electic Medical College. Compiled from the Official Register in the office of the Prothonotary of the Court of Common Pleas of the City and County of Philadelphia, verified and corrected up to date. Arranged alphabetically and by sheets.

IT ALSO CONTAINS

Lists of Veterinary Surgeons, Pharmacists and Dentists, and information about the Nurses Directory, Army and Navy Services in the city, Hospitals, Asylums, Medical Charities and Dispensaries, Medical Societies; Colleges of Medicine, Pharmacy, Dentistry and Veterinary Surgery; Ambulance and Emergency Services, Quarantine Regulations, City Board of Health, Vaccine Physicians, Massage Manipulators. Full particulars about the Registering of Births and Deaths, with the statistics of the past year, etc., etc.

PRICE TO BE FROM $1.00 TO $1.50.

ORIGINAL LECTURES.

HEAD-INJURIES ACCOMPANIED BY PARALYSIS.

A Clinical Lecture, delivered at Bellevue Hospital.

BY FREDERIC S. DENNIS, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK CITY.

GENTLEMEN: The first case which I shall introduce to you this afternoon is that of a child, whom you saw in the clinic last Saturday suffering from complete hemiplegia. If you refer to your notes, you will find that this little boy, three months since, sustained a compound fracture of the skull, by falling from a great height, and that after the depressed bone was elevated the child recovered. During the past few weeks he has not been feeling well, suffering from slight headache, elevation of temperature, and acceleration of pulse. He has lost his accustomed appetite, has become exceedingly irritable, and does not sleep well. The wound upon the head appears unhealthy, and discharges a small quantity of sanious pus. These symptoms have gradually become exaggerated, and have finally resulted in complete hemiplegia, in which condition you saw the child at my last clinic. The history of the case, I then told you, pointed to an intracranial abscess beneath the site of the original wound. That diagnosis was correct, for considerable pus was discharged through the opening made last week. Last Saturday this little fellow was completely paralyzed upon the side opposite to his head-injury. The child has gradually improved daily, and, as you see, can move the leg and the arm, and now the nurse will let him down from her arms, and you observe that he is able to walk out of the clinic, and also to raise his arm sufficiently to seize the hand of the nurse.

This, then, is a typical case of paralysis which was caused by pressure of pus upon the brain, and I will avail myself of this case to base a few remarks upon the question of "Trephining for the Relief of Paralysis in Head-injuries."

You know that in my didactic lectures I told you that compression of the brain with paralysis was due to some kind of pressure, of which *bone*, *pus*, *blood*, *foreign body*, were the chief causes, and you remember that each cause was considered at length with the diagnostic symptoms. In the clinic to-day I will show you cases illustrating these four causes of paralysis, in order forcibly to impress upon your minds the lessons which were then inculcated. I further remarked, in connection with this subject, that at times it was very difficult to establish a correct diagnosis, even with good data to aid and with symptoms well pronounced. Since lecturing to you upon that subject, I have met with a case illustrating in a striking manner the uncertainty and difficulty of making a diagnosis, and I will refer to the patient in the way of a short digression, as the case seems especially pertinent.

A man was struck upon the side of the head two weeks before admission into the Ninety-ninth Street Reception Hospital, and although he was unconscious a few minutes after the blow, he soon regained consciousness and was apparently well for over a week, when he had symptoms very similar to those described in the case of the little boy, who, a week ago, was paralyzed, but to-day has just walked out of the clinic. When the ambulance brought the man to the hospital, he was in coma, and had complete hemiplegia upon the side of the body opposite to the head-injury, the evidences of which were manifest locally, and the fact of the injury was corroborated by the testimony of his friends. The question of abscess of the brain as a result of the head-injury suggested itself to me, considering the hemiplegia and coma following two weeks after a severe blow with a club upon the head. The operation of trephining was indicated, but before deciding upon this step I had the temperature taken and the urine examined. There was slight elevation of temperature, but not sufficient to indicate formation of pus. The urine was heavily loaded with albumen and contained casts. I deferred the operation for these two reasons, and the autopsy upon the following day revealed the wisdom of the course of non-interference, for the case proved to be one of ordinary apoplexy, or hemorrhage into the corpus striatum, occurring incidentally with a severe blow upon the head, which injury perhaps may have acted as an exciting cause to develop the apoplexy.

Thus you see, Gentlemen, that while the history of the case would naturally suggest compression from pressure due to pus as the cause of the hemiplegia, and indicate the use of the trephine, the absence of sufficient elevation of temperature, and the presence of a considerable amount of albumen and casts pointed to another probable cause for the hemiplegia. The case of the little boy and that of the man, from a clinical point of view, are of great interest, as illustrating the principle and impressing the lesson of examining carefully and thoroughly into every case, and of using every means at hand in order to establish a correct diagnosis before attempting any surgical operation upon the head.

These two cases further present for your consideration two of the four causes of paralysis, namely, *pus* and *blood*, and although no operation was indicated to relieve the paralysis in the case where the blood was the cause of the hemiplegia, yet you are not to understand that an operation is not indicated where there is a surface clot in head-injury, and this leads us to the fact that blood may cause paralysis in one case and no operation can be performed, while in another case an operation may relieve the hemiplegia, and the cause still be from pressure of blood.

I will present to you, next, a case in which *bone* was the cause of the paralysis, and which will further afford a most beautiful example of cerebral localization. This patient, whom you all now see, and whom some of you saw when he was trephined, has the following history: He was working in a cellar when a paving-stone fell

upon him from a height of twenty feet, striking him on the head. He was seen by the ambulance surgeon, Dr. Keene, of St. Vincent's Hospital, a few minutes after the injury, when he was found to be quite conscious, but for a minute exhibited clonic convulsions of the left arm. These movements were not afterwards repeated, but were succeeded by chilly sensations. His pulse was regular and about seventy to the minute, his respirations were rapid, and his pupils were normal. There was a contused, lacerated wound over the right side of the head, at about the junction of the parietal with the temporal regions. From this wound there was profuse hemorrhage, and at the bottom of the wound the bone was felt to be markedly depressed. When admitted to the hospital the right pupil was wider than the left, and sluggish in its action; the pulse was slower, about sixty to the minute, and bounding; the respirations were deep and noisy, the extremities were cold, and the patient perfectly conscious. There was partial paralysis of the left arm; he could not flex or extend the elbow, but could, with difficulty, partially abduct the limb from the side. He complained of severe pain in the muscles of the neck, especially on the left side. He was placed immediately under ether and the wound in the scalp was enlarged, which exposed a stellate depressed fracture; the fragments were raised into position, after removing a small portion of bone with the Hey's saw, and sixteen pieces were taken out of the skull from the bottom of the wound. The exposed dura mater was uninjured, and the brain was seen pulsating beneath it. The wound was cleansed and dressed with carbolic lotion, one to forty, and in a short time healed by granulation, with a firm cicatrix. The paralysis at once subsided after the operation, and his temperature, pulse, and respiration remained about normal during convalescence.

This patient is one of the most interesting cases to illustrate paralysis from pressure of bone. The case is highly instructive for this purpose; but when you study it more closely you see at once a rich field of inquiry open to you. It is a case illustrating recent views concerning cerebral localization, and on account of the rarity of these cases and the accuracy of the diagnosis, you will at once perceive that it is one of the few cases recorded of cerebral localization from pressure by bone. Some valuable contributions of this nature are found in Nothnagel's well-known work, *Topische Diagnostik der Gehirnkrankheiten*, Berlin, 1879; also by Ferrier, and the writings of Charcot and Pitres in various French journals. In the *Revue de Médecine* Charcot and Pitres are now publishing a series of most interesting articles. Experiments on animals are much less conclusive as regards the localization of functions in the human brain than are well-observed pathological cases in man. It is established by the researches of Charcot and others, that the motor part of the cerebral cortex in man embraces the central convolutions, the paracentral lobules, and a part of the adjacent convolutions. According to Charcot and Pitres, there are motor centres for the opposite side of the face in the lower part of the central convolutions, particularly of the anterior central; motor centres of the arm in the middle third of the anterior central convolution; and centres for the opposite upper and lower extremities in the paracentral lobule and upper parts of the central convolutions. The separate centres for the opposite lower extremities appear, according to Charcot, to be in the paracentral lobule; but they have not been so accurately determined as those of the upper extremity, because cortical paralysis confined to the lower extremity is very rare. Cortical paralyses may be in the form of total hemiplegia, of associated monoplegias (as paralysis of one arm and of one side of the face), or of pure monoplegias (as paralysis of the arm alone).

The most common example of a pure monoplegia due to cortical lesion is brachial monoplegia, or paralysis of one arm. In brachial monoplegia of cortical origin, the lesion is situated in the middle third of the anterior central convolution. Now, Gentlemen, this case before us, on the table to-day, was one of pure brachial monoplegia. The lesion therefore would be of the middle third of the anterior central convolution. There was no paralysis except that of the left arm. This case before us is one of great value, as showing the importance to a surgeon of the knowledge of recent studies in cerebral localization—also for the clear and precise nature of the symptoms and their strict localization. The ataxia which existed for a short time after the paralysis disappeared was interesting, and was probably due to a temporary disturbance in the nutrition of the motor centres. Upon this brain, which is hardened in nitric acid, you see the exact point of pressure which caused the brachial monoplegia in the brain of the patient, who is here in the clinic to-day.

The fourth and last cause of paralysis from head-injury is due to the presence of a *foreign body*, as a bullet, piece of iron, or any other hard substance which has been driven into the brain. I now show you several such bodies which others and myself have removed, and which foreign bodies have been the cause of paralysis.

This completes the four causes of paralysis from head-injury, but before dismissing this most interesting subject I must avail myself of another case, which I now introduce to you, and which was one of paralysis with no injury of the brain, but an injury to the spinal cord.

This man was brought to the Ninty-ninth Street Reception Hospital by the ambulance on account of an injury sustained by a heavy bank of earth caving in and falling upon his back. He suffered from paralysis of his left leg, and from anæsthesia of his right leg, both of which symptoms occurred shortly, although not immediately, after the accident. His bladder was also paralyzed. I made the diagnosis of spinal hemorrhage, and the history of the case has confirmed the diagnosis. This case illustrates a very interesting and rare form of paralysis, due to an affection involving the spinal cord. This form of paralysis is called spinal hemiplegia, or spinal hemiparaplegia, according as the arm and leg are both affected, or the leg alone is involved. We owe to Brown-Séquard most of our knowledge upon this subject. His conclusions are based upon experiments upon animals, and afford an admirable example of the importance of such experiments. Brown-Séquard has proved that if one lateral half of the spinal cord be cut across in the dorsal or in the lumbar region, there results paralysis of motion in the lower extremity on the same side as the lesion, with loss of sensation, or anæsthesia of the opposite lower extremity. This condition is called hemiparaplegia. If the lesion affected the lateral half of the cord in the cervical region, then the arm and the leg on the side of the lesion are paralyzed, and the condition is called spinal hemiplegia. In the

extremity with paralyzed motion, sensation is intact, or may be even exaggerated (hyperæsthesia).

In the patient before us we found incomplete paralysis or paresis of the left leg, which, however, retained its sensibility, and, in fact, for a few days seemed to be hyperæsthetic. In the opposite leg motion was perfectly normal, but there was marked loss of sensation, although not complete anæsthesia. The loss of sensation was made evident by pricking the skin, and by the use of the æsthesiometer. The case therefore belongs to the class of spinal hemiparaplegias described by Brown-Séquard. These symptoms developed soon after his injury, which was caused, as I have already mentioned, by a bank of earth falling upon his back. We cannot be positive as to the nature of the lesion, but it seems probable that a small hemorrhage occurred in the spinal meninges, and caused pressure upon one lateral half of the cord. This was the diagnosis I made at the time of the accident, and the rapidity of his recovery, as well as the manner of his recovery, would indicate this as the probable lesion, the symptoms disappearing as the blood was removed by absorption. Such cases are extremely rare. They illustrate the important physiological fact that the motor fibres do not cross to any considerable extent in the spinal cord, while the sensory fibres cross throughout the whole course of the cord.

This unique combination of cases, all occurring about the same time, has enabled me to bring before you in a striking and forcible manner the question of trephining in head-injuries associated with paralysis, and also the question of paralysis in injuries of the spinal cord. Spinal hemiparaplegia, from its infrequency, and the group of cases illustrating all the causes of paralysis in head-injuries, form a most important theme for study and reflection, and if they only prove to illustrate the great principles which have been insisted upon in the didactic lectures, of which the clinic to-day is an attempt to impress by illustration, I shall be content with the hour's work; and in concluding this part of the subject let me add that much is yet to be learned in this important domain of surgery, and I trust that the exhibition of these cases will increase your zeal in the study of paralysis arising from surgical causes.

Before dismissing this important surgical topic, there is still one other principle I would like to illustrate. You remember that in my didactic lectures I told you that in compound fractures of the skull, where the trephine is indicated, the prognosis depends not so much upon the extent of the fracture of the bone, as upon the question of the amount of injury done to the contents of the skull. The same surgical axiom holds good in cases of fracture of the pelvis; it is not the fracture of the bone so much as the injury to the pelvic organs which influences the prognosis. To recur to our first proposition, and to strengthen it by several living illustrations, I introduce first to you the patient whom some of you saw operated upon at the Ninety-ninth Street Hospital. This patient, who has kindly consented to come to my clinic to-day, is a man who sustained a compound comminuted fracture of the frontal bone, produced by the kick of a vicious horse. It is sufficient to say that sixty-four pieces of bone were removed from a wound which embraced nearly the entire forehead. Many of these pieces were large, and the extent of the comminution made it necessary for the house-surgeon, Dr. Fergusson, to take away most of the frontal bone. The contents of the brain appeared uninjured, and the man to-day is perfectly well, and is engaged at his usual avocation. The second case is one whom you now see, and from whom thirty pieces of bone have been removed, owing to a compound comminuted fracture of the skull produced by direct violence. In this man's case the contents of the skull were not injured, and this fact made the prognosis good, whereas, otherwise, it would have been most serious.

The third case, which I now show you, is one in which I trephined for persistent headache of six years' duration, and after removing a circular plate of bone over the seat of an old depressed fracture, the symptoms entirely disappeared, and the patient has been entirely free from the severe pain, the cause of which was revealed by the operation to be pachymeningitis externa. There was no injury to the brain itself, and the operation consequently was attended with no danger. These cases, together with others which I have operated upon from time to time, only strengthen the truth of the statement, that, with the dura mater uninjured, and the brain itself undisturbed, the prognosis is always good. In conclusion, it is surprising to learn how many eminent surgeons have been, and are even now, opposed to the use of the trephine. Notwithstanding the favorable results from trephining which you have seen from time to time in this clinic, yet there are surgeons who still decry the operation. In Mr. Gamgee's recent work on the treatment of fractures, one of the most valuable contributions made to the surgery of this subject, and a book which I am sure you will study with great profit and pleasure, you will find a most interesting chapter upon this very question of trephining. He shows that there is still a very wide diversity of opinion among eminent surgeons upon this point, and that while during the last century the trephine was used extensively, Desault, a French surgeon, was the first to oppose its use. Percival Pott, an English surgeon, on the other hand, urged its indiscriminate use. John Hunter, Pott's most illustrious pupil, advocated its use, and there were then two distinct classes—on the one side Desault, John Bell, Astley Cooper, Abernethy, Liston, and others argued against its use; on the other side Pott, Hunter, Guthrie, Brodie, Velpeau, and others argued in its favor. This great controversy influenced in different countries the number of the operations. Thus, during ten years from 1855, there were reported only four cases of trephining in France, while in England during the same period there were reported, according to Le Fort's analysis, one hundred and fifty-seven cases. The late Mr. Callender stated that the trephine had not been used for six years in St. Bartholomew's Hospital, though Mr. Callender was the successor of Percival Pott, through such a lineage as Abernethy, Lawrence, and Paget. This change in the very hospital which was formerly the arena where the trephine was so frequently resorted to, is as strange as it is significant.

When we consider how frequently trephining was performed in very early times, and with success, assuredly in these days surgeons should not hesitate to perform an operation which holds out such good prospect of recovery. During the Stone Age, Prof. Broca has informed us that trephining was practised by the ancients with only pieces of flint, and with these rude instruments they scraped the bone until a disk was removed sufficient

to expose the dura mater. Mr. Blaker, of London, in a very valuable historical contribution says, "considering the class of cases, the desperate nature of the operation, and the barbarous method of performing it, to say nothing of the after-consequences, *e. g.*, hemorrhage, blood-poisoning, erysipelas, the danger of injury to the brain, the want of proper nursing, and bad hygienic surroundings generally, it is wonderful that any one patient recovered; and yet, incredible though it seems to be, Dr. Prunères states that out of twenty skulls in his possession (all of which were trephined during life) nineteen of them exhibit indubitable signs of having recovered from the operation." He further states that these disks of bone were worn as amulets and considered as talismans to ward off disease. Where the patient died, the amulet was attached to the body as a sort of talisman to ward off evil spirits in another world. Prof. Broca adds that this is one of the earliest indications we have recorded in history "of the belief in a life beyond the grave."

Thus you observe, Gentlemen, that the operation which you have witnessed in the clinic is of very great antiquity, and with the resources of modern surgery the operation should be free from danger.

With the great diversity of opinion upon the question of trephining, I am not surprised that many of you are in doubt as to which course to pursue. My advice to you in this matter, as in many other difficult questions in surgery, is to be guided not by history, nor by tradition, nor by single authority, for often these guides mislead and misdirect. History, and tradition, and authority may not be trustworthy guides for you in these great emergencies. Let your actions be governed by the individual circumstances which arise in connection with each particular case. Consider every case by itself, and where the indications which I have already given you are present, trephine; but where they are absent adopt the plan of non-interference. The subject of the manner in which the operation is to be performed will be considered in our demonstrative course upon the cadaver; and now, Gentlemen, I will say no more to-day upon the question of trephining, but leave this subject for you to reflect upon and carefully to study over, in the hope that the few hints which I have given you may awaken a new interest in a surgical theme as trite as it is important, and as difficult as it is fascinating.

ORIGINAL ARTICLES.

ON DIGITAL EXPLORATION OF THE BLADDER IN OBSCURE VESICAL DISEASE;

WITH ITS RESULT IN THIRTY-TWO CASES.

BY SIR HENRY THOMPSON,

SURGEON EXTRAORDINARY TO H. M. THE KING OF THE BELGIANS; CONSULTING SURGEON AND EMERITUS PROFESSOR OF SURGERY TO UNIVERSITY COLLEGE HOSPITAL; PROFESSOR OF PATHOLOGY AND SURGERY TO THE ROYAL COLLEGE OF SURGEONS, LONDON, ETC.

No one who has had much experience in the treatment of maladies affecting the urinary organs will deny that he occasionally meets with a case, the nature of which, however closely it is studied, is not determined by the ordinary methods of investigation. Nevertheless, it must be conceded that our diagnostic means and appliances are numerous and efficient; and, furthermore, that a large portion of the urinary apparatus may be reached without difficulty and be examined in various ways.

These methods comprise palpation and percussion externally, the use of the sound and catheter internally, and an examination of the characteristic secretion, the urine, physically, chemically, and microscopically.

Extensive as these resources are, a certain proportion of patients, larger perhaps than is generally supposed, receive treatment for long periods of time, such as months or even years, without any satisfactory diagnosis having been made of their cases. Of course, when they are described or referred to, recognized forms of technical phraseology are employed, affecting to indicate, if not clearly to express, the pathological significance of their symptoms. Thus they may be attributed to some affection of the kidneys or to "chronic pyelitis," or to "chronic inflammation and congestion of the bladder," while the specific character of them is sometimes said to be "gouty," an epithet which, manifestly appropriate in some instances, is as manifestly suggestive of uncertain diagnosis in others.

Thirty years of practice have made these facts but too obvious to myself, and for a large part of that term I have diligently labored to cultivate in the classroom and elsewhere a high appreciation of the art of diagnosis, in regard of which I may perhaps be allowed to refer to my clinical lectures, oral and published. But some five or six years ago, I came to the conclusion that, keen and careful as we might be, the cases of urinary disease which defy analysis are so numerous and so important as to demand a further method of investigation than they had hitherto received; and I resolved to make a bold experiment for the purpose of accomplishing it. I determined on searching the bladder, if possible, with the finger itself, when the sound and other means enumerated had failed to inform me, and when the symptoms were so grave as to demand a knowledge of their source, and probably some efficient surgical action, in order to give a chance of life to the patient.

The first question naturally arising was, will it be possible to accomplish this completely in many, or indeed in a moderate proportion, of these obscure cases? There proved to be no difficulty in the dead body: and, with anæsthesia, I thought there ought to be none in the living. And having well considered both the suprapubic and the perineal routes, I adopted the latter, introducing my finger as far as to the internal meatus, by means of a limited perineal urethrotomy, without section of the prostatic urethra, finding that this afforded me an unexpected facility in obtaining that intimate knowledge of the interior of the bladder which I sought.

The operation which I have now so often practised, is simply what I have called it, external or perineal urethrotomy; the well-known incisions, but less extensive, which have long been employed for the division of stricture, etc. An operation practised by our own Richard Wiseman, in the

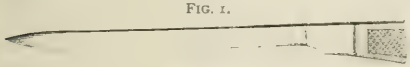
seventeenth century, described also nearly at the same period by François Tolet, and subsequently by Colot, Petit, Ledran, and several others, as the Boutonnière, by which name it has long been familiarly recognized in France.

But my proceeding, almost identical in regard of incision with this (for anatomical conditions being unchanged, new routes to the bladder are not now discoverable), has a new object, and has been proved competent to discover and to treat conditions never so discovered and treated before. It is the object and the achievement of the proceeding which are new, and not the incisions by which they are attained. Further, even the incision would not alone accomplish what is necessary, and could not do so until the discovery of anæsthetic agents enabled us to induce *complete relaxation of the abdominal muscles*, and thus to prosecute an inquiry not otherwise possible.

I will now describe the method which my present experience has led me to adopt, and point out some of those details in prosecuting it which are the most important.

The patient having been secured in the usual position for lithotomy, and rendered insensible, a rather short median-grooved staff is carried into the bladder and held by an assistant. The knife to be employed should be straight, the blade very narrow and about two and three-fourth inches long. *Vide* Fig. 1.

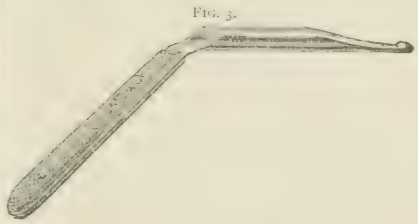
FIG. 1.



Natural size.

With this the operator makes a vertical incision of the skin in the line of the raphé, an inch and a quarter long, and terminating below about a half or three-quarters of an inch above the anus. Placing his left index finger, palmar surface upwards, in the rectum, so as to inform himself of the upper limit of the bowel, he introduces the knife with its cutting edge upwards, horizontally, into the wound until he reaches the groove of the staff, which should thus be struck about the junction of the membranous with the bulbous portion of the urethra. When contact is verified, the puncture of the canal is lengthened a little with the point of the knife, which is then withdrawn, incising in the act perhaps some of the tissues, so as to enlarge the wound towards the external orifice, but avoiding as far as possible injury to the bulb. A director resembling a small median gorget with blunt edges (the size and form of that which I use is drawn in Fig. 2, is passed into the groove of the staff and serves as a guide to the left index, which is insinuated into the

FIG. 3.

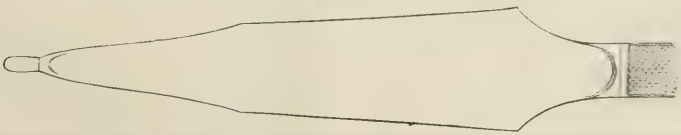


The same seen sideways.

prostatic urethra, and gently pressed onwards until the tip, slowly dilating it, enters the neck of the bladder. Arrived at this point, the operator should stand up, demanding the full effect at this moment of the anæsthetic agent, and with his right hand, press very firmly above and behind the pubic symphysis. By concerted movements between the left index finger and the right hand, he may now bring seriatim, every part of the interior of the bladder over the point of the index, and scrutinize the lining membrane so as to learn its physical condition to the minutest particular. If there is the smallest growth, recess, or inequality of any kind, or even roughness, an adhering scale, or small calculus, it is recognized with ease and certainty. Occasionally when the subject is very fat, and the prostate large, considerable pressure is necessary to make the exploration complete, and now and then it may be impossible to reach the whole interior, as I have found in one case only. But if the relaxation of the abdominal walls is absolute, it is surprising how far the contents of the pelvis, with the aid of an assistant, may be, by continued forcible pressure, brought down towards the perineum, and thus within reach of the operator's finger.

If, in the examination of the bladder a growth is encountered, the surgeon should devote two or three minutes to deliberately estimating its exact size, form, and density; its position in the bladder, and whether others are present also. He should do this again after he has reseated himself, with and without suprapubic pressure by his assistant, so as to be thoroughly acquainted with the situation of the growth. Then, withdrawing his finger, he introduces slowly a pair of forceps, straight or curved according to his judgment, to the spot, holding lightly a handle in each hand, when he will almost certainly seize the growth if he be careful and deliberate in his movements; much in the same way as he would in

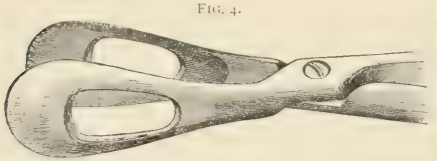
FIG. 2.



Outline of director intended to be of the natural size: but it is erroneously drawn, at least a line too wide at the broader end.

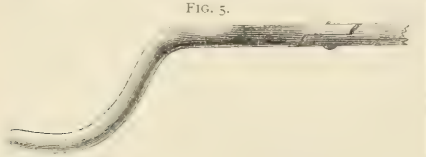
seeking a nasal polypus. Having assured himself that he has a fair hold, he is not to drag or tear out the body, or even much twist the forceps, especially if the material is dense, or he may injure the bladder itself. I find it better to "jamb" or "mash" together (if I may so describe the act) the rough margins of the forceps, before I endeavor to withdraw, and effect separation thus if I can. If this is not easily accomplished, I introduce the left index and complete the separation with the finger-nail if possible, which is sometimes a very efficient instrument. Proceeding thus, partly by forceps, of which I have employed numerous forms (see Figs. 4, 5, 6, and 7), partly with the finger, the removal of the

FIG. 4.



Straight forceps, which meet by serrated edges. The blade of the original instrument measures nearly seven-eighths of an inch wide.

FIG. 5.

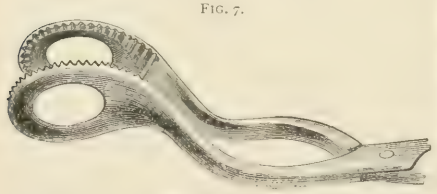


Small curved forceps, seen sideways; for growths close to the neck of the bladder.

FIG. 6.

The above forceps, seen from the front, showing separation of the blades to avoid nipping neck of the bladder.

FIG. 7.



Another form of curved forceps for seizing tumors springing from the sides of the bladder. The edges of all the forceps meet by serrated or roughened edge for the purpose of effecting a separation by the action described in the text. I have a duplicate set, the edges of which are cutting, for use with great care where the tissue is particularly firm, and on two occasions I have found them useful. The first named, however, should be employed if possible.

mass may be safely accomplished, entirely so if the growth or growths be simple and pedunculated; less completely when the base is wider, employing the forceps several times, carefully removing as much as possible piece by piece; and but very imperfectly if the tumor is mammillated and not at all pyriform in character. In the female I have sometimes slowly brought it within view, and have put on a ligature.

I think it is not unlikely that a small, slender écraseur, threaded with a flexible wire, stout catgut, or wire gimp, may be useful in some cases where single, but rather wide, peduncles are presented. Such an instrument has been made for me, and can be used by the side of the finger without requiring additional space, since the diameter of the shaft only equals that of a No. 10 catheter (English guage); but I have not used it yet.

There is one source of danger which I would point out, and which must be carefully guarded against. It may happen during the operation, that the assistant is required to press very firmly above the pubes, so as to bring the growth nearer to the operator. By doing so at this stage, it is quite possible that the upper part of the bladder may be inverted and pushed downwards in a fold, presenting itself toward the operator as an eminence, and be mistaken for a large polypus or growth, an error which might be fatal. The possibility of the occurrence should not be lost sight of; hence my admonition above to examine the bladder not only with, but without the influence of pressure, and so as to ascertain precisely what is to be removed before any attempt to do so is commenced. After the removal, whatever the result may be, a stout India-rubber tube about five or six inches long and the diameter of the little finger, is secured in the wound to wash out the débris and to serve as a channel from the bladder to some vessel placed for the purpose. Hemorrhage is usually free for a few hours and gradually subsides. If the tube causes irritation, it may be removed soon; if not, it may remain a day or two.

My entire experience up to this date may be summarized as follows: I have explored the bladder in thirty-two cases of obscure disease; four in the female, twenty-eight in the male, finding and operating for tumor in fifteen cases, two in the female and thirteen in the male. No extension of the incisions described was necessary in any case; in two of the cases (still living) no attempt was made to remove the mass, since the form of it rendered the achievement impossible, salient portions only were taken off. If a tumor, unusually large, demanded either extended incision or a suprapubic opening—but this must be a very rare occurrence—the operation should be thus continued, provided of course that the tumor is so formed as to admit of removal, otherwise extended incision would be unwarrantable. Eight of the cases of tumor are living at the present moment, at periods after the operation ranging between three years and six months. Three died soon after the operation, the others at various terms of several months, from reappearance or secondary malignant growth. Almost all form preparations in the museum of University College.[1]

[1] Twelve of the tumors were exhibited, as well as microscopic sections from them, to illustrate a paper read by the author at the Royal Medical and Chirurgical Society of London, in June, 1883.

In the other cases impacted calculus or other unusual conditions were met with, and the relief in some of them was conspicuous and remarkable. Obstinate chronic cystitis with large deposit of triple phosphates, and associated with frequent catheterism for atonied or obstructed bladder, was greatly relieved in several instances, and is indeed one of those forms of disease in which the proceeding may be often highly serviceable, if the tube is retained for a week or so, the urethra and the bladder being at rest during that period.

This brief summary of my experience warrants me, I think, in believing, and I trust my brethren will agree with me, that the proceeding described will enable us to prolong life in many cases, and to avert disease completely in some, where, without such aid, it must inevitably prove fatal.

NOTE ON THE VALUE OF ELECTRICITY IN SOME AFFECTIONS OF THE SKIN.

BY G. BETTON MASSEY, M.D.,
ELECTRO-THERAPEUTIST TO THE PHILADELPHIA ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

THOUGH this therapeutical agent is sometimes referred to in treatises on diseases of the skin, I am led to call especial attention to it at this time from a belief in the infrequency of its employment by dermatologists, and also in order to point out, very briefly, important differences that exist in the indications for the use of galvanism and other forms of electricity.

Now, I do not think that faradism can ever hold a prominent place in this connection. It is true that we have in faradic electricity, when properly applied, a means for powerful stimulation of the sensory nerves of the skin, yet I do not see that this can be of much practical value in the diseases in question. As a means of physiologically treating anæsthesia, pruritic symptoms, and other sensorial disorders it is unequalled, but when the disease is intimately connected with alterations of the nutrition it is manifestly powerless. When faradism is applied to the skin it should invariably consist of the rapidly interrupted current, and be applied in such a manner as mainly to confine its action to the surface. Such a purpose can be accomplished by selecting any bright, dry, metallic surface as the active electrode, some other portion of the patient's body being connected with the indifferent electrode, which should be well moistened. Instead of a smooth surface for the active electrode, I have for some time preferred to use an ordinary wire hair brush so altered as to admit of the current traversing the wire bristles when the brush is connected with the battery.

Franklinism has seemed to me to be similar to faradism in its action on the skin, with this difference, viz., franklinic sparks have a much more irritant effect, causing first a contraction of the elastic tissue, blanching, and the production of "goose flesh;" followed quickly by a decided relaxation, redness, and congestion, which latter condition may persist some hours. A daily continuance of the application will result in the production of an acne-like eruption. I am not aware that franklinism has ever been used by dermatologists, and would merely suggest to them the possibility of this very decided action having a therapeutic value.

It is, however, in galvanism that we have a promise of great usefulness in some of these affections, due mainly to its action in producing electrolysis, as well as stimulating ordinary tissue change, and thus altering the trophic processes in parts acted upon. For this end we can alone rely upon the constant galvanic current, passed with gentleness directly through the diseased portions of skin by a well-moistened electrode, preferably the cathode, the similarly moistened anode being applied to some other part of the body. Its alterative potentiality when thus applied may be readily inferred from a reference to its action in health.

When healthy skin is brought under the influence of the moist poles of a mild current, sensations of burning and tingling are very soon produced, and increase steadily in intensity as long as the current is allowed to continue or remains bearable. This continuous increase in intensity during the application is found with no other form of electricity, and is due to the changes produced in the skin during the passage of the current that tend to make the upper layers a better conductor. As the application continues we have, therefore, an increasing current passing through the circuit, and the increase of pain and redness admonish us that we may lessen the number of cells employed towards the close of the sitting, and yet have a greater amount of current than at the beginning. As a rule, it will be found that the sensation of burning presents an excellent measure of the amount of current passing. Not so, however, with the tingling; this varies greatly in different parts of the body, and in different situations on the same member, and is due to the accidental inclusion of sensory nerves in the influence of the poles. In addition to these sensations, and increasing *pari passu* with the burning, there will be found a decided redness under the poles, gradually becoming wheal-like in character, and, if the application is continued, eventuating in a decided blister.

The time consumed in these changes, taking a fixed number of cells for comparison, depends more on the character of the skin of the individual or of the part than it does on the distance between the poles. As an illustration, it may be said that in most individuals much more current will pass through a circuit including the body from the inner surface of one forearm to one of the popliteal spaces than will pass through a circuit made by placing the poles two inches apart on the back.

These considerations are important in connection with therapeutic applications, as conditions of disease greatly alter the conductivity of the derm—generally increasing it—and render a current strength that would be unfelt in health a powerful factor for good or evil.

In regard to the differing actions of anode and cathode on the skin, I will affirm the truth of the

following: A more irritant action possessed by the cathode; a peculiar blanching of the skin that precedes the redness under the cathode; and a brighter tint of redness produced by the cathode than by the anode. Beyond these facts I would not at present care to go.

As illustrations of the therapeutic value of galvanism in two of these affections, I will append brief summaries of three cases that occurred in my practice.

The first case was the wife of a farmer, who suffered from periodical attacks of intense neuralgic pain in the right hand extending up the arm as the paroxysm attained its height. Coincident with the decline of the attack (generally several days from its commencement) an herpetic eruption would appear at the seat of greatest pain, occupying an area an inch and a half in diameter in the middle of the dorsal surface of the hand. Occasionally a spot, one inch in diameter, in the middle of the palm would be the seat of the eruption instead of the back. This case being turned over to me by Dr. S. Weir Mitchell, for treatment at the Electrical Clinics of the Infirmary for Nervous Diseases, careful anodic galvanization was practised for some weeks, with the result of controlling greatly the eruption. The paroxysms of pain remained as bad as ever, however, and the case was only cured subsequently by division of the nerves supplying the part.

The second case illustrates the therapeutic value of the method in a much bolder light. A prominent member of the profession, in this city, called on me recently with a history of recurring attacks of eczema of the right upper lip. The attacks came on suddenly and generally lasted nearly a month, the lip becoming much swollen, painful, and productive of intense discomfort. Various plans of treatment had been tried by eminent brother practitioners, but all to no purpose. On this particular occasion he was especially desirous of averting the attack that had just begun, and came to me with the request that I would try galvanism. Cathodic galvanization was immediately begun and practised twice daily for something over a week. The first application caused a change in the sensations of the part and started an improvement which culminated in entire recovery a week later.

The third case was more chronic in character, but presents an equally happy termination. The patient, a member of the bench of a southern State, aged about sixty, had suffered from an eczematous eruption on the right hand for eight months. After fruitless attempts to eradicate the disease his physician sent him to me. Direct applications of the cathode to the diseased surface were begun, the electrode being held in contact as long as a gentle current could be borne—generally from two to five minutes. The patient's time being limited, these sittings were repeated thrice daily for twenty days, at the end of which time the disease had entirely disappeared.

1502 ARCH STREET

REMOVAL OF A SHAWL-PIN FROM THE TRACHEA BY OPERATION.

BY J. D. STRAWBRIDGE, M.D.,
OF DANVILLE, PENNA.

ON July 25, 1881, George S., a bright, active child of five and a half years, was left for a few moments to amuse his infant sister, and lay on his back on the floor, with the head of a small steel shawl-pin in his mouth, which was inhaled and lodged in the larynx. The mother saw him choking, ran to his assistance, thrust her finger into his throat to remove the cause, and forced the pin wholly into the windpipe, thereby relieving his breathing, but bringing on violent fits of coughing. The father, who was employed near by, was called at once, and brought the child in his arms to my office. After hearing the statements of the parents, who both asserted that they had felt the point of the pin with their fingers during fits of coughing, I took advantage of one, which soon occurred, to search the throat carefully with my finger, but failed to discover the presence of the pin. Although the child's face was flushed and swollen, the eyes suffused, breathing oppressed and wheezing, and cough frequent, I was still in doubt as to the pin having entered the larynx. I assured the parents that its removal from the windpipe could only be effected by an operation, but advised delay until its presence there could be positively ascertained, unless dangerous symptoms occurred, in which event I would operate at once.

Dissatisfied with this expectant course, the patient was carried about from one physician to another, until nearly every one in the place had been consulted. Each in turn having examined the throat and failed to find any trace of the pin, discredited the statements of the parents, and did not believe that a pin had been inhaled at all.

For two weeks after the accident, the health remained good, and but little inconvenience was experienced, except the cough and slight dyspnœa; after that time the fits of coughing became more severe, with increasing mucous expectoration and difficulty of breathing, followed later by chills.

On Saturday, August 27th, the parents came again to me with the child, and insisted upon an operation, notwithstanding the advice of their family physician, who assured them that it could do no good, and would only cause the death of the child. Finding the child's health becoming seriously impaired, and a fatal termination probably not far distant, I decided to operate, and appointed the following Monday morning, August 29th, for that purpose.

The patient was brought to my office; the anæsthetic was administered by Dr. Pursel, and Drs. Ogleby, Ammerman, Graul, and Mausteller being present. Assisted by Messrs. Neil and Hoffman, medical students, I commenced the operation by an incision through the skin from the cricoid cartilage to the sternum. To expose the trachea as low as possible required a very deep and careful dissection, as the neck was very short and thick. Very little

trouble was experienced from bleeding during the dissection, or from the division of the isthmus of the thyroid, which was found necessary. Two very large veins, united by a transverse branch at the lower end of the incision, covered the front of the trachea, and were the cause of considerable difficulty in its exposure. In attempting to detach and press them to one side, the left vein was injured, and had to be ligatured both above and below the cut. These veins, which I at first supposed were the inferior thyroids, I am now convinced were an anomalous development of the anterior jugular veins, and supplied the place of the external jugulars, which could not be found. The trachea was drawn up, and opened as low as possible; four of the rings were divided. The pin was readily found, and grasped with a pair of forceps. I attempted to carry it upward in the trachea, expecting to bring the head easily out through the incision, but was unable to move it either up or down. Seeing no alternative, I had an assistant take hold of the pin as low in the incision as possible with a second pair of forceps, while I maintained my hold above, and with a strong narrow-bladed bone pliers cut the pin between them. The point was easily withdrawn, but in cutting the pin the head portion was forced from the grasp of the forceps, and drawn by a strong inspiration into the bronchia. While casting about to select a suitable instrument, inversion of the patient was proposed by Dr. Pursel, and tried, but without effect.

The patient was returned to the table, and, having selected a long, slender pair of polypus forceps, the curve of which admirably adapted them to the purpose, I commenced to search for the lost portion of the pin. Expecting it had followed the most direct route, I passed the closed jaws of the instrument into the left bronchus, and searched carefully along its walls, until I could distinguish its principal division. Satisfied that it was not there, and that, from the size of the head, it could not possibly have gone further, I withdrew the instrument until I could enter the point in the right bronchus. Feeling carefully down this tube for an inch and a half or more, I struck the head of the pin. Slightly opening the jaws of the forceps, and turning them about, I was able, after a little search, to grasp the shaft of the pin. Knowing well that an attempt to withdraw the pin would probably result in serious injury to the bronchus, by forcing the shaft of the pin into its walls, unless the point was held in the jaws of the instrument, I drew the forceps back, feeling carefully along the shaft, until it had several times passed the end, and I was satisfied I held the point in the forceps. Applying gradually some little force without moving it, I was for a moment startled by the thought that the pin had been forced into the walls of the bronchus; but an instant's reflection assured me that this could only have been done by the forceps, and not without the pin having been moved from its original position, which had not been done.

Renewing my efforts, a little more steady traction brought the head suddenly from its position with a distinct sound which was heard by my assistants, and was withdrawn without further difficulty. The head of the pin, which was three-eighths of an inch in diameter, had been drawn into the bronchus at the commencement of an inspiration, and lodged against the first division, where it completely closed the passage, forming a perfectly tight valve, and prevented any further access of air to the right lung. The pin measured two and a half inches in length. The child breathed well by the natural passages after the extraction; and after he had returned to consciousness, a small fold of lint was laid over the incision, retained by a strip of adhesive plaster, and a light handkerchief tied about the neck. On the following morning the wound was closed by adhesive plasters, and in two weeks was entirely healed. The child has remained well up to the present time, perfectly free from any laryngeal complications, although three children of the family had previously died from croup.

MASTOID NECROSIS, MENINGITIS, DOUBLE OPTIC NEURITIS, AND ATROPHY OF BOTH OPTIC NERVES IN A CASE OF SUPPURATION OF THE MIDDLE EAR.

BY CHARLES SHAFFNER, M.D.,
ASSISTANT SURGEON TO THE EYE AND EAR DEPARTMENT OF THE PHILADELPHIA DISPENSARY.

ON October 29, 1883, G. M., girl, eleven years old, applied for treatment at the Eye and Ear Department of the Philadelphia Dispensary, suffering from a very interesting form of eye disease, which was due to a disease of the ear, which latter had existed for some time.

Five and a half years ago suppuration of the right middle ear set in, with severe earache. After the suppuration had existed for four weeks inflammation of the mastoid occurred. During this time she was treated at her home by her physician with syringing the right ear with warm water and poultices to the mastoid, which caused the abscess to break, and soon after this facial paralysis came on. She was sick seven months in her own home, and then went to a hospital. Soon after this she lost her sight, and was blind for six weeks. Maniacal delirium set in and would last for two or three hours at a time; kept up for three weeks, and was very severe, it being necessary to hold the patient down in bed. There was severe pain in the right side of the head, and all the symptoms of cerebral meningitis. She was treated with ice and cold dressings to the head.

In addition to the blindness, divergent strabismus now came on, while the sight began to be spasmodic, coming and going for two months, and then gradually improving up to the time of her visit to the dispensary. Three pieces of bone were discharged, one from the external auditory meatus and two from the mastoid region. Suppuration from the right external auditory meatus has kept up until now, and the mother, under advice, has only endeavored to keep the ear clean.

At the time of her entrance into the dispensary on

October 29th, she presented the following condition: O. D. V. $= \frac{10}{CC}$. She read some words in Jaeger's No. 8 type. Hypermetropia 1.5 D. Right disk was greenish-white in color, and its upper border was obscure. There was a crescent one-sixth of the size of the disk to the outer side. The right retinal vessels were small. O. S. V. $= \frac{6}{CC}$. She saw letters in Jaeger's No. 14 type. Hypermetropia 1.5 D. The left optic disk was greenish-white, and there was pigment on the disk. There was a white crescent in lower part of the disk equal to one-eighth of its diameter. Left retinal vessels were small. Both eyes were then in an advanced stage of optic nerve atrophy. The right ear was still suppurating rather freely, and the marks of the former mastoiditis could be seen in a large depressed scar behind the right auricle. The patient is still very dull and of rather feeble intelligence. She was ordered cod-liver oil, the suppurating ear was treated, and the patient kept under view.

The case is of great interest, as showing what serious complications can arise from an ordinary suppurating ear, and as showing such a clear chain of inflammation from the ear to the eye; first the mastoid trouble took place, then cerebral meningitis followed, to be succeeded by double optic neuritis, most probably descending neuritis, and that by atrophy of the optic nerves. It very seldom occurs to an eye and ear surgeon to see these two organs connected by such a sequence of events, and for that reason this case has been thought worthy of being noted.

HOSPITAL NOTES.

THE CINCINNATI HOSPITAL.

(Service of ROBERT SATTLER, M.D.)

INTERESTING CASES FROM THE OPHTHALMIC WARDS.

Reported by F. O. MARSH, Resident Physician.

RUPTURE OF THE ZONULA OF ZINN, WITH DISLOCATION OF THE LENS INTO AQUEOUS CHAMBER.

CASE I.—John G., æt. 57, stone-cracker, while engaged at his work, five weeks before coming into the house, was struck in the left eye by a large fragment of stone. The accident was followed by immediate loss of sight and great pain in the injured eye. Three weeks subsequently the pain subsided somewhat, and vision partially returned for objects at the periphery of the field. On coming into the house, October 5th, no external injury could be detected, but the eye was considerably injected and painful. The pupil was dilated to the utmost, and fixed, only a narrow rim of iris being visible. The lens was dislocated in its capsule into the anterior chamber, and completely cataractous. Between the rim-like iris, and the periphery of the opaque lens, which still preserved its original size and shape, could be seen a narrow belt of pupil. Intraocular tension + 2. Ordered salicylate of eserine gr. j aq. ʒij, instilled every four hours. No influence was exerted upon the iris, except that the pain was relieved and the intraocular tension was diminished.

October 15.—The lens was extracted through a lower linear section of the cornea, the knife being passed through the lens in making the corneal incision. Ordered absolute quiet in bed, and a compress bandage over both eyes. Subsequently a mild solution of boracic acid was used as an antiseptic lotion. Though the operation was attended with slight loss of vitreous humor, very little reaction followed.

COMPLETE LUXATION OF THE LENS IN ITS CAPSULE, BY SLIGHT PERCUSSION, INTO VITREOUS CHAMBER.

CASE II.—M. F., æt. 64. Had always had good sight, according to his own statement, with no symptoms to call attention to his eyes till one week before presenting himself to the clinic, when he had fallen on the floor from a sofa while asleep. The accident was followed by immediate loss of sight in the left eye. On admission to the clinic the lens could be seen luxated in its capsule, and lying in the bottom of the vitreous chamber completely opaque, and very movable. The iris was tremulous, the vitreous completely disorganized, and with the ophthalmoscope a large number of floating opacities could be seen moving readily back and forth through the pupillary area, between the anterior chamber and the vitreous, the whole interior of the eye being thrown into one common chamber. No pain or reaction; vision absent.

INJURY TO THE EYE WITH THREATENED PANOPHTHALMITIS; SYMPATHETIC TROUBLE; ENUCLEATION.

CASE III.—George H., admitted October 8th, colored, æt. 22, steamboat hand.

Two days before admission was struck in the right eye with a sharp stick, inflicting a contused and lacerated wound, extending vertically completely across the cornea, and penetrating also the iris and lens. Lacerated iris tissue and a small amount of opaque lens substance were protruding from the wound in the cornea. Lids swollen; chemosis of ocular conjunctiva excessive. Intense pain had existed in the injured eye since the accident. Dr. Sattler removed the protruding and mangled iris tissue, and evacuated the opaque lens substance. One-quarter grain of morphia was administered hypodermically in the right temple, and a four grain solution of atropine instilled into the eye every four hours; subsequently, a two grain solution every three hours; rest in bed, and ice applications.

October 9.—Slept well, pain much less, chemosis undiminished. Ordered equal parts unguent. hydrarg. and unguent. belladonnæ applied to right temple every four hours. Applied three leeches; ice applications continued; mercurial purge at bedtime.

10th.—Chemosis much less; pain subsiding; corneal wound gaping and edges vascular, but no tendency to suppuration. The opaque lens matter was completely removed.

24th.—Corneal wound healing, with slight indrawn condition of the corneal cicatrix, though the ball still preserves its rotundity; vision reduced to perception of light.

November.—The pain and inflammatory symptoms continued to subside until Nov. 16, when pains in and

about the eye again commenced. The injured globe became the seat of exquisite sensitiveness, and manifested, on pressure, the characteristic ciliary or point pain. A few days after this, the uninjured eye manifested all the signs of sympathetic irritation, and on November 20th these symptoms were so threatening and pronounced that enucleation of the injured eye was performed.

UNFORTUNATE RESULT OF A BADLY EXECUTED STRABOTOMY.

CASE IV.—Annie M., æt. 43, admitted October 17th, is very myopic, and also amblyopic. States that many years ago an operation was performed on both eyes by a travelling doctor to relieve a slight degree of strabismus convergens, which only existed at times. Ever since the operation she has been unable to turn her eyes from side to side without moving the whole head. At present, both eyes diverge enormously, with no power to move either eye, even to the median line. The right eye is more prominent than the left, but both eyes are exophthalmic. Double vision has never at any time existed, but sight has been very defective.

October 20.—An advancement operation of the internal rectus muscle of the right eye was made, together with a tenotomy of the external rectus. Ordered ice applications, rest in bed, and a firm compress bandage to both eyes.

24th.—Removed the stitches; no reaction exists; patient possesses the power to move the eye well beyond the median line; exophthalmus less pronounced.

REMARKS.—Case I. is interesting on account of its comparative rarity; rupture of the zonula of Zinn and dislocation of the lens entire in its unbroken capsule, being unusual in an eye free from previous disease. It is perhaps not a little remarkable too that, considering the necessary violence of the injury, rupture of the sclerotic did not occur. The fact that the luxated lens acted as a foreign body, causing considerable pain, and producing secondary glaucoma, rendered its removal imperative. The operation of course differed from the ordinary cataract extraction, in that no iridectomy was required. On the contrary it was a desirable object, yet a point which was not attained, to contract the iris by the use of eserine into a barrier behind the lens to prevent its recession backward into the vitreous, during the attempt at extraction. The operation was performed by making the corneal puncture a little back of the sclero-corneal limbus, and then by a quick movement spearing the lens thus preventing its escape into the vitreous during the completion of the corneal incision. The lens was then readily expelled by the ordinary manipulation. At present, she counts fingers with a + 3½ lens, and sees objects about the room. No rupture of the choroid exists. The iris is still dilated, and two distinct rents are visible as the result of the passage of the lens into the anterior chamber.

In Case II., in contrast with Case I., it is interesting to note, that a pathological process must have been progressing for a length of time previous to the accident, without any apparent inconvenience to the patient, yet of such a nature as to allow the complete luxation of the lens in its capsule by a comparatively slight percussion. The eye being perfectly non-irritable, no interference was instituted.

In Case III., owing to the extensive character of the injury, including a lacerated cornea, iris, and lens, a kerato-iritis of a suppurative character, or even panophthalmitis and subsequent phthisis bulbi, was imminent; but by a timely interference and the use of rest, cold applications, leeches, etc., immediate danger and more protracted suffering were avoided, and the untoward results threatening seemed to have been warded off. The hope of obtaining a perfectly non-irritable eye, free from the danger of inducing sympathetic trouble, was in this case, in spite of the careful removal of the iris tissue and removal of the lens, thwarted by the rapid and violent development of sympathetic irritation of the fellow-eye, which necessitated the prompt removal of the injured one.

Case IV. is an unusually striking example of the unfortunate results that may follow a badly executed strabotomy, where the muscle is divided too far from its tendinous insertion, and the power of convergence altogether destroyed, thus causing a deformity much more serious than the original squint. The operation of advancement was attended with great difficulty, owing to the atrophied and shrunken state of the rectus internus muscle. An endocapsulitis had also existed, doubtless as the result of the previous operation, causing extensive adhesions between the capsule of Tenon, the sclerotic, and the tendon of the rectus externus.

These circumstances, combined with an unusually thin sclerotic, made tenotomy of the external rectus extremely difficult. The advancement of the external rectus was made by passing a double thread through its tendon and the conjunctiva at that point, and bringing it well forwards and stitching to the conjunctiva above and below near the corneal margin. It should be added also that the existence of a high degree of myopia (12 D.) makes it evident that the strabismus for which the original operation was performed was apparent rather than real, and was not due to, or associated with, excessive power on the part of the internal recti muscles.

MEDICAL PROGRESS.

THE OPERATIVE TREATMENT OF PROLAPSE OF THE UTERUS.—At the meeting of the Medicinische Gesellschaft, in Giessen, on May 1, 1883, DR. KALTENBACH spoke of the results of the operative treatment of this affection as opposed to the treatment by means of pessaries, etc. The latter, he said, are seldom satisfactory for complete retention of the prolapsed organ, and must be often changed; moreover, there is the danger of bad consequences from too great pressure. The operative treatment is easily carried out, and, with the proper antisepsis, is almost entirely devoid of danger. Of more than one hundred cases of operation for prolapse, he has had only one case of severe sickness.

The operation should only be performed on recent cases and slight degrees of dislocation; it should not be performed on very old people, as the anæsthesia and the subsequent confinement are dangerous.

Kaltenbach reported the case of a women aged sixty-one years, in which the usual orthopædic treatment had completely failed. The vagina was totally inverted, and the thickened bladder wall and Douglas's pouch extended to the extremity of the prolapse. At the first operation,

one and four-fifths of an inch of the supra-vaginal neck was excised. Three weeks later, colporrhaphy and colpo-perinæorrhaphy were performed. The case was a complete success.—*Berliner klin. Wochensch.*, Nov. 19, 1883.

EUCALYPTUS IN GANGRENE OF THE LUNGS.—DR. BONAMY relates the case of a man, about fifty years of age, who was admitted to hospital suffering from cough, dyspnœa, and fever. A few days after admission, the fetid odor of his breath became so extreme that it was necessary to separate him from the other patients. There was dulness in the axillary line on the left side over the middle portion of the lung. At this point there was tubular respiration, and crepitant râles were audible at the end of inspiration. The sputa consisted of a black matter, detached portions of which were swimming in an abundant serous fluid. The cough was incessant, and the odor intolerable. A diagnosis was made of gangrene of the lung of superficial extent. The patient was first put upon a mixture containing carbolic acid, but no improvement following, this was replaced by tincture of eucalyptus. In two days after the last prescription the odor of the breath was much less offensive, and in less than two weeks the patient was cured.—*The Practitioner*, Dec. 1883.

ALIMENTATION OF CHILDREN AFTER TRACHEOTOMY.—PROF. SAINT-GERMAIN, in a recent article on this subject in the *Revue Mensuelle des Maladies de l'Enfance*, gives directions for the proper feeding of children upon whom tracheotomy has been performed. The children generally refuse food, and are consequently deprived of the means of building up the strength.

This is due to several different causes; one of the first is the bad disposition of the child, which has not been sufficiently controlled. Pain on deglutition is another, often caused by the wide and deep eschars produced by the cauterizations so frequently and unwisely applied by a great number of physicians. Others again, especially in an advanced stage of the disease, are affected with paralysis of the palate which makes deglutition impossible, as all liquid food is regurgitated through the nose.

M. Saint-Germain has employed, in all these cases, a procedure which has been recommended and used after surgical operations on the mouth or tongue which incapacitate the patients swallowing. A caoutchouc sound of medium calibre is introduced through one nostril, and passed into the stomach. Through this, milk, bouillon, wine, and other liquid foods may be injected—such as are employed in ordinary practice when a liquid diet is necessary.

This procedure has been used a large number of times at l'Hôpital des Enfants, and has given most excellent results. It is easily performed, there is no danger of making a false passage, and the canula already in the trachea precludes the possibility of the sound going into that passage.—*Bull. Gén. de Thérap.*, Nov. 30, 1883.

BROMIDE OF ETHYL AND NITRO-GLYCERINE IN NERVOUS DISORDERS.—PROF. O. BERGER has found bromide of ethyl useful—(1) In neuralgic conditions of the nerves of the face and head, in megrim, and in nervous headache and heaviness. The inhalation of twenty to forty drops of the remedy several times a day has lessened headache in cases in which quinine, salicylic acid, caffein, and guarana had all proved useless; and in three cases of headache connected with cirrhosis of the kidney, it was better than any other remedy. (2) In neurasthenia; it is here given in doses of from one to three grammes twice or thrice a day if necessary. (3) In epilepsy; here it is of very little use, although Bourneville and D'Ollier considered it useful. They narcotized their patients daily for ten to twenty minutes with it, but when given in doses of one gramme daily by inhalation it is useless. It is besides expensive, and causes much depression. When inhaled before or during the epileptic attack, it only prevents it or cuts it short in exceptional cases. (4) In hysteria it is of more use. The attack of hystero-epilepsy may sometimes be cut short by narcotizing with it for ten or fifteen minutes, eight to twelve grammes of the drug being required. When given in doses of a half gramme to two grammes by inhalation once or twice a day, it may avert a threatened attack of hystero-epilepsy. (5) In several cases of psychical excitation the bromide of ethyl has proved serviceable. The author finds nitro-glycerine also useful in headache. —*The Practitioner*, Dec. 1883.

SOLID TUMORS OF THE ROUND LIGAMENT.—A recent number of the *Archiv für Gynäkologie* contains a careful paper on this subject by DR. M. SÄNGER, of Leipzig. These tumors belong to the connective tissue group, their structure being that either of myoma, fibroma, sarcoma, or a combination of these. The author has collected twelve such cases, to which he adds a hitherto unpublished one of his own. In situation, he points out, they may be either *intra-peritoneal*, that is, growing from the part of the round ligament which is within the peritoneal cavity; *intra-canalicular, i. e.*, in the inguinal canal; *extra-peritoneal*, that is, arising from the round ligament outside the inguinal canal; or they may grow from the abdominal wall, in such proximity to the origin of the round ligament that their connection with that structure may be inferred. The third, or extra-peritoneal variety, are the commonest. Most of them are fibroid in structure. In eight out of ten of Dr. Sänger's cases the tumor was on the right side; and he asks, "Does this arise from causes similar to those which cause a greater frequency of inguinal hernia on the right side?" He cannot trace a predilection for any particular age. All the patients had borne children. The growth of these tumors is usually slow; during pregnancy they seem to increase with greater rapidity, and during the lying-in period to undergo a temporary retrogression or involution. The only exciting cause that Dr. Sänger can find, and this only in one case, is long-continued or severe pressure. The growths themselves appear to cause no symptoms until they get large, and then they may be painful and tender, and cause symptoms by pressure or dragging on other parts, such as dysuria, ovarian pain, constipation, abdominal and sacral pain, etc. They may thus deteriorate the general health. The diagnosis is extremely difficult; and there hardly seem to be sufficient grounds for formulating any diagnostic points. The only treatment of these tumors is removal. This is called for not only on account of the symptoms they cause, but also because of their liability to accidental injury and inflammation in consequence of their superficial situation.—*Medical Times and Gazette*, December 1, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 5, 1884.

THE MICROCOCCUS OF PNEUMONIA.

THE micrococci of pneumonia, as described by FRIEDLANDER and FROBENIUS in their recent researches as abundantly present in the exudate into the alveoli in the acute form of the disease, and in the lymph passages of the affected lung, are, in most instances, surrounded by a more or less thick capsule, which is stained pale blue in gentian violet and fuchsin. The capsule is frequently broader than the coccus itself, externally sharp contoured, and adapts itself to the shape of the latter, being elliptical or circular as this happens to be. Two adjacent micrococci may be surrounded by one capsule, producing an elongated ellipse. In other organisms, again, the central coccus is completely wanting. The pneumonia-cocci are, however, never found in zoöglœa masses.

On account of the different reaction of the capsules, their solubility in water and alkalies, and their insolubility in acids, Friedlander believes that they are composed of mucin or a closely allied substance. The capsules are most easily and quickly demonstrated by staining the dry preparation with a solution of aniline and gentian violet. The cover glass, on which the preparation has been dried, is placed for half a minute in alcohol, by which the ground-substance is quickly and the capsule and cocci more slowly decolorized. The preparation is then placed in distilled water, in which it may be studied, or preserved in Canada balsam or damar. The cocci may also be stained in eosin.

Such a capsule-formation as this, in which the individual micrococcus is surrounded by a well-marked gelatinous capsule, has not previously been observed in cleft fungi; or at least in no other micro-organisms found in the human body is a gelatinous capsule of such decided thickness found as in the pneumonia-cocci.

The capsule-bearing micrococci have also been found in the pneumonically infiltrated lung-tissue itself, very abundantly in the pleuritic and pericardial exudate, as well as in the serous infiltrated pleuritic adhesions in cases in which these were the result of a preëxisting pleurisy. They were also found in the non-infiltrated, but œdematous, parts of both lungs when there was pneumonia of one lobe only, death occurring in the stage of acme. On the other hand, they were not found in the blood or other organs. In several cases of true croupous pneumonia, which had lasted more than six days, true cocci were found in the blood, but no capsules. In other instances, only a part of the cocci were provided with capsules. But in other fresh cases, where death occurred during the advance of the disease, the capsules were invariably present. It may, therefore, be said that the capsules correspond to the highest stage of development of the fungus, and are a necessary product of the living phenomena of the organism.

Culture-experiments demonstrated that the micrococci exhibited some peculiarities in the different animals. In the pneumonia of men it will be remembered that there were differences in size and structure of the cocci. In the mouse the cocci are considerably larger than in man—from two to three times the size. In guinea-pigs they are usually smaller than in mice, but have, on the other hand, a very broad capsule. In dogs they are about the same size as in man. In all species there are found more frequently than in man, along with the cocci, rod-shaped bodies of different length, but mostly as long as the double coccus, and always surrounded by the characteristic capsule.

The important bearing of these new observations if confirmed, on the cause and nature of pneumonia, is evident. To many who have had clinical experience with this affection, it will not be a surprise to find facts adduced which lend support to the view that it is an infectious disease, for there have not been wanting features in the clinical history of many cases which favor such a view, while some observers have long been satisfied as to its infectious nature. Among these, we believe, is Prof. Austin Flint, Sr. The bearing of these views upon the prophylaxis and treatment of pneumonia has yet to be determined; but there is reason to expect that both may be materially modified if it be eventually determined that it is an infectious disease.

SANE OR INSANE? REPORT OF THE MEDICAL COMMISSION ON THE CASE OF JOHN McGINNIS.

JOHN MCGINNIS, convicted of the murder of his mother-in-law, and now awaiting the death penalty, is alleged to be insane. A commission appointed by the Governor of Pennsylvania, consisting of Drs. Jones, Moon, Mills, Andrews, and Morton, have been engaged for several weeks in investigating the case, and have terminated their labors by a majority and a minority report, the latter signed by Dr. Morton. As regards the composition of this commission, it may be well to state that three of them—Drs. Jones, Moon, and Mills — are alienists and neurologists, Dr. Andrews is a physician and surgeon, and Dr. Morton is a surgeon. There were no medical or surgical questions, apart from the mental condition of McGinnis, to be decided.

The majority report, signed by all except Dr. Morton, is emphatic in declaring that McGinnis is insane; that he has "delusional monomania," and "chronic alcoholic insanity." The reasons for this conclusion are given in detail. The family history of the criminal is marked by a strong neurotic tendency, and he has exhibited from an early period peculiarities of mind and very pronounced moral obliquity. He had been addicted to drink, to other vices, to crime. The report very justly maintains that a disposition to vice and crime is an evidence of mental unsoundness, rather than of superior powers of mind. But the proof of his insanity is the existence of delusions of suspicion and persecution. Up to the time of his incarceration, his sole delusion was of "marital infidelity;" afterward he became suspicious of his counsel and spiritual advisers, and subsequent to his conviction he had hallucinations of sight and hearing; he had visions and heard voices. Such is the case of the majority.

The minority report, made by Dr. Morton, is a clear and strong presentation of fact and opinion, and is, it need hardly be said, the antipodes of the majority report. Dr. Morton questions the accuracy of the family history told by those interested in saving McGinnis from the shame of the gallows; and he denies the correctness of a diagnosis which confounds a mad, but not causeless, jealousy with a systematized delusion. As regards the hallucinations of sight and hearing, and the delusions of suspicion and persecution, they are held to be feigned; McGinnis, at the time of the Guiteau trial, having expressed himself confidently as able to simulate insanity more successfully, and these symptoms of mental derangement having manifested themselves since his trial ended.

As the counsel for McGinnis did not enter the plea of insanity in his defence, nor in the argument for a new trial, the prominence given to this point since his conviction rather indicates, as Dr. Morton suggests, that it is an afterthought—an inspiration born of an urgent necessity. Up to the time of McGinnis's arrest and conviction, the only evidence of mental derangement consisted in the "delusion with reference to marital infidelity." There can be no doubt that the psychosis called chronic alcoholic insanity is marked by the presence of delusions connected with the sexual relation. The so-called delusion of McGinnis does not, however, conform to the usual clinical definition of that affection. It was not marked by the hallucinations of the sexual functions, so characteristic of alcoholic insanity. McGinnis was simply madly jealous, and not without reason, according to the evidence of reliable witnesses. Furthermore, his supposed delusion does not appear to have been preceded by the usual alcoholic delirium, nor by those somatic derangements belonging to chronic alcoholism. If the doctrine of insane delusion be interpreted according to the ruling of the majority report, many persons now considered sane are fit for asylum restraint. McGinnis had an insane delusion because he could not be convinced of the purity of his wife. The believer in ghosts or in spiritual manifestations must also have a delusion, because he holds to the truth of certain hallucinations, regarded as such by the most of mankind, and of the falseness of which he cannot be convinced. McGinnis's belief in the infidelity of his wife, had been a delusion, if coupled with other insane conceptions related thereto; if, for example, he was convinced that his sexual organs had been bewitched by the machinations of his wife's paramour. It is not alleged that previous to the murder, McGinnis associated any hallucination, whatever, with his notion of his wife's unfaithfulness.

Since the original report was made, a supplementary communication has been addressed to Governor Pattison by the majority, setting forth that McGinnis has now distinct hallucinations of hearing, and, to some extent, of vision, and reaffirming their opinion. If these symptoms are not feigned—admitting their genuineness—they have diagnostic value now, only as throwing light on the question of responsibility at the time when the crime was committed. For these reasons we believe that Dr. Morton's objections to the theory of chronic alcoholic insanity, which is put forward in the majority report of the Commission, are well founded, although the conclusion at which they have arrived may be correct.

The mental symptoms which have appeared subsequently to the trial; the delusions of suspicion and persecution; the hallucinations of sight and hearing, and an ecstatic religious state are, in the majority report, regarded as genuine manifestations of the alcoholic psychosis, but, in the minority re-

port, held to be feigned. The unsystematized delusions of persecution consist in a vague distrust of his lawyer and of his spiritual advisers; but if every man who fails in gratitude to those who have befriended him unsuccessfully, must be laboring under an insane delusion, then surely must our conception of insanity be greatly expanded. Although it is true, as stated in the majority report, that malingerers feign either acute maniacal delirium or dementia, McGinnis, who had studied the Guiteau case, might be expected to act with more acuteness, and conceive a higher ideal of mental perversion. The coincident appearance of these hallucinations with the efforts to procure a mitigation of sentence, is, at least, a suspicious circumstance, for surely his counsel would not neglect such an opportunity had these mental symptoms existed before the trial. But, considered of themselves, the hallucinations at this period, as well as before the trial, as above stated, were not in harmony with the clinical characteristics of chronic alcoholic insanity, for in this malady the delusions are usually connected with the sexual organs, indeed, we may say almost invariably when marital infidelity enters into the insane conceptions.

In the suggestive report of Dr. Morton, the business capacity of McGinnis is insisted on as an evidence of his responsibility. Although insanity is not incompatible with the possession of considerable powers of mind, responsibility before the law involves many considerations. We have always maintained in these columns, that capacity to distinguish right from wrong, and the will power to do the right and avoid the wrong, should constitute the criterion of responsibility. John McGinnis knew the nature of the act he intended to commit, and the consequences; the law gave him the power to obtain redress for any wrong done by his wife; he choose to execute vengeance in his own way, and thus deliberately accepted the consequences. Had he heard a voice from Heaven, in the genuineness of which he believed, and in response to which he acted, he must be considered irresponsible before the law and in the judgment of all alienists and jurists; but his auditory hallucinations had no connection with the commission of the crime.

HIGH AMPUTATIONS FOR SENILE GANGRENE.

AT a recent meeting of the Royal Medical and Surgical Society, a most important question was raised by MR. JONATHAN HUTCHINSON on the treatment of senile gangrene, or that form of mortification which is due to calcification of the arteries, by amputation of the limb at a good distance beyond the seat of the lesion. In gangrene of the toes and foot, the lower third of the thigh should be selected, and the middle of the arm in the rare cases in which the hand is affected.

The practice advocated by Mr. Hutchinson has been taught in this country for many years by the elder Gross, who based it upon the fact that the disease in the vessels of the lower limb, as demonstrated post-mortem, extends at least as high as the popliteal artery. He, however, maintains that we should await the formation of the line of demarcation, while Hutchinson advises that the operation should be resorted to as soon as the patient is sufficiently ill to take to his bed, and the affection is well established.

Senile gangrene and dry gangrene are not synonymous. In the large majority of cases our own observations confirm the statement of Mr. Hutchinson, that it is moist. Hence, if the case be allowed to pursue its own course, death generally ensues from septicæmia before the line of demarcation is formed, spontaneous recovery, especially when the affection extends beyond the toes, being a curiosity. In a smaller proportion of cases the fatal result is due to exhaustion and pain.

For these reasons we regard the recommendation of Mr. Hutchinson as being most timely and rational, and the opinion of those who took part in the discussion was also, as a rule, favorable to the practice. In this country, the younger Gross has invariably insisted, in his lectures, upon early and high amputation to prevent septic infection. The only objection that can be urged against the procedure is the danger of amputation of the thigh in old subjects, but the risks are, at the present day, reduced to a minimum by the employment of anæsthetics, Esmarch's bandage, and aseptic precautions. Our firm conviction is that everything is to be gained by throwing aside old traditions and superstitions in the management of senile gangrene. Left to itself, the disease rarely terminates in recovery; if amputation be performed near the seat of the trouble, the flaps are liable to die; if performed early and high up, amputation is likely to save life, as in the cases recorded by Hutchinson, James, Dix, Rivington, and Godlee.

DIGITAL EXPLORATION OF THE BLADDER.

In the current issue of THE MEDICAL NEWS, SIR HENRY THOMPSON calls attention to a mode of exploring the bladder in cases of obscure disease, through which the existence of suspected lesions may be accurately determined, and the proper remedies be applied for their relief. In systematizing the procedure, he has done for the male what Simon, of Heidelberg, upwards of seven years ago, did for the female. It will be remembered that the latter surgeon rapidly dilates the urethra with specula of

hard rubber, if necessary up to a diameter of four-fifths of an inch, through which he is enabled to explore with the finger the entire inner surface of the organ. Simon's operation is as free from danger as the median perineal incision in the male, and is not followed by incontinence of urine.

In nearly one-half of the explorations made by Sir Henry, tumors were detected, and more or less thoroughly removed with the instruments described in his valuable communication. The wonder is that neoplasms existed in so many cases, and if the proportion be found to be as great after a more extended experience, it will be of great aid to the surgeon in diagnosticating tumors in obscure vesical disease.

CATHETER FEVER.

ON December 13th, at the Medical Society of London, SIR ANDREW CLARK read a characteristic paper on "Catheter Fever," which was the occasion of a most remarkable discussion. The whole of the matter appears to us to lie in a nutshell. About 1865 Sir Andrew Clark evidently saw a case of what Sir Henry Thompson and other surgeons would call continued or chronic urinary fever. This case died, and at the autopsy Sir Andrew found no lesion whatever of the renal tissues or ureters, but the bladder was hypertrophied, and the seat of a sloughy inflammation. All the constitutional signs of the disease of which the patient had died, had ensued on the use of the catheter at the commencement of what Sir Andrew would term "catheter life." It is important to mention that in the case in question, the patient passed water too frequently; the urine was of low density, and although it contained no albumen, it might possibly have been the urine of a man the subject of chronic Bright's disease.

Having narrated a typical case of catheter fever supervening on undoubted prostatic enlargement and "overfull" bladder, Sir Andrew gave a most instructive historical account of "fever" resulting from surgical interference with the urinary organs. He showed how such a fever had been recognized by physicians in the very beginning of the present century, how Velpeau in 1841 had made post-mortem examinations in such cases, how Marx, and later on Malherbe, Henry Thompson, Fayrer, and others had studied the question. It resulted from all this that many observers of repute had been as unable as Sir Andrew himself to discover alterations in the kidneys of certain cases. It was not denied that many of the cases had died with well-marked signs of interstitial nephritis, as Marcus Beck had so ably and conclusively shown. But Sir Andrew contended that there were a limited number of such cases which could not be written down as examples of death from renal disease.

This question of the involvement or not of the renal organs, evidently is the pivot round which the whole controversy turns. Is Velpeau wrong, are Marx and Malherbe wrong, is Sir Andrew Clark wrong? Now, with all due respect to the great authorities mentioned, we must give it as our unqualified opinion that these observers are in error. And for the following reasons: Velpeau's work having been done forty years ago, we submit that, from a correct histological point of view, it cannot be of any value because of its age. The methods of histological research have improved so vastly; we know so much more of the normal and abnormal appearance of tissues than we could have done forty, twenty, nay even ten years ago. And we say this in a judicial spirit. We have every belief that these observers spoke the truth so far as they knew it. But we repeat that what we want, is some sections made by Velpeau or Marx or Sir Andrew, or any other individual, taken from the renal organs of patients who have succumbed to the continued form of urinary fever. Let us examine these sections, and let us declare that there is nothing morbid in their texture, and we will humbly apologize for our present disbelief in the facts themselves. We feel firmly convinced that in these examples we should find microscopic evidence in the shape, say of little collections of leucocytes in the interstitial tissue of the renal organs.

Sir Henry Thompson made a most excellent, judicious, and exhaustive speech on the question, repeating most lucidly his views as contained in his work on the *Diseases of the Urinary Organs*. Mr. Berkeley Hill had never failed to find interstitial nephritis in autopsies made by himself or in those performed in University College Hospital during the past few years. Mr. Scovell Savory also gave a very good address, in which he advocated the claims of some of the cases to be regarded much more as resulting from nervous disturbance, of the nature of prolonged shock, than of septicæmia. Mr. Reginald Harrison advocated the septic view of the disease.

THE ACCIDENT TO GENERAL GRANT.

AS GENERAL GRANT stepped from his carriage in front of his residence in New York on the evening of December 24th, he slipped on the ice and fell, striking heavily upon the outer and upper portion of his left thigh. The pain was extreme, and the inability to use the limb complete. The fall, the age of the patient, and the subjective symptoms suggested probable fracture of the neck of the femur, and the incomplete examination of the limb, which alone was possible at first because of the pain, did not entirely exclude this diagnosis. After the lapse of thirty-six hours the pain subsided, and then a

thorough examination made by Dr. Fordyce Barker and Dr. L. A. Stimson, who are in attendance, failed to discover any objective signs of fracture.

The injury, we are authoritatively informed, appears to have been a severe contusion of the outer and upper portion of the left thigh, with possible rupture of muscular fibres or attachments in the effort to avoid the fall.

On Monday, the 31st, the General was able to sit up for some time, and his early recovery is confidently anticipated by his physicians.

REVIEWS.

HEART AND SCIENCE. A STORY OF THE PRESENT TIME. By WILKIE COLLINS.

FICTION has been used more than once already in that fight against certain ways of increasing our knowledge which is called the "Anti-Vivisection Movement." Once there was that original assertion which the "Zoöphilists" made that Harvey had never used living animals in his researches. Again, they said that Sir Charles Bell had made his most famous discoveries without vivisection. Of course these agitation-mongers never thought it worth while to verify their references to these authors. But lately fiction has been brought to the aid of the movement in a different and more legitimate way, in the shape of a novel,[1] in which Mr. Wilkie Collins, with all his characteristic energy, has come to the assistance of the cause.

That Mr. Collins should write an "antivivisection novel" is proper enough, and no doubt it pays him well: that the old arguments should be repeated is natural, because there are no new ones. Clear reasoning or true logic is scarcely to be looked for, because the whole agitation against experiment has become a sort of religion of faith—a belief, a matter of sentiment simply, not a result of reasoning processes. Even those of the believers who will argue the queston at issue are like the Scotchman who was "open ta conveection but wad like to see the mon that could conveence him." We expect then none of these things in the book—but we may reasonably assume that in a "novel of purpose" the characters are intended for types of their classes. Accordingly we find two medical types—the hero and the villain of Mr. Collins's tale. The hero, Mr. Ovid Vere, is a young physician of extraordinary abilities, and a most commendable tenderness of heart. That he should faint when the villain treads by accident upon a beetle is perhaps praiseworthy, and that he should turn pale and tremble at the mention of "vivisection" is perhaps not to be wondered at, considering the subject and object of the book. His superhuman abilities are manifested by his publishing the MS. bequeathed to him by a mulatto physician whom he has attended on his death-bed in Quebec. This work contains the solution of that obscure problem in the treatment of "brain disease" to which the villain has devoted years of labor and many "vivisections." This same problem, Mr. Collins tells us, "has thus far been the despair of medical men throughout the whole civilized world."

The second typical character is the wicked doctor, a "vivisector," who, like all who seek by the aid of experiment to increase knowledge, is tall, dark, hideously ugly, and so utterly without moral sensibility of any kind that he allows the cousin and betrothed of the hero, who falls ill in his absence, to grow worse and worse in order that he may study the uncommon phase of disease which she represents, to wit, simulated paralysis of a hysterical nature, and he thinks it very strange that the lover on his return should be angry. Dr. Vere has brought with him his legacy of knowledge from Montreal. Certain cases related in the book are, of course, precisely like the girl's and he is enabled to effect her cure. The preface of the great treatise is quoted against the "useless and detestable cruelties which go by the name of vivisection." On reading further we find his subject is hysteria. It is very probable that all the additional knowledge of the treatment of hysteria in a human female that he could have derived from the examination of a dog's brain, would scarcely have repaid his trouble. When Carmina is recovering, Mr. Vere is much amazed and alarmed to find a lapse in her memory of some days—not an unusual incident in severe hysterical cases. Finally, the villanous vivisector, Dr. Benjulia, finding himself forestalled in his grand discovery, makes his will, leaving everything to Vere's half-sister, of a child of whom he is fond. Mr. Collins allows him one human feeling—turns loose the animals from his laboratory, shuts himself up with a laudanum bottle, fires the uilding, and so dies. "His brethren of the torture-table attended the funeral in large numbers."

Now what a muddle of nonsense is all this! We have too much respect for Mr. Collins's abilities to suppose that he seriously intended these people for types, or these screams of abuse for argument, nor do we think that he really believes most or many students in experimental science to be like Dr. Benjulia. We rather think that the novelist, looking about him for a subject, seized upon one of the English crazes of the moment to supply fuel for the boiling of his own pot.

He does produce one argument, other than simple abuse, against vivisection, under which name he apparently includes all experimental research. Let us examine it for a moment; it is formulated thus:

"The law which forbids you to dissect a living man allows you to dissect a living dog. Why? There was positively no answer to this. Suppose he said, Because a dog is an animal? Could he, as a physiologist, deny that a man is an animal, too? . . . . Because the dog is the inferior creature in intellect? . . . . But the lower order of savage or . . . . lunatic, compared with the dog, is the inferior creature in intellect: . . . . the dog has, on your own showing, the better right to protection of the two. . . . . Because . . . . a dog is a creature without a soul? . . . . How do you know? . . . . If the law, in the matter of vivisection, asserts the principle of interference, the law has barred its right to place arbitrary limits on its own action—if it protects any living creature, it is bound, in reason and in justice, to protect all." (Chap. XXXII.)

The arguments are hollow, and the conclusion absurd and inconsequent. Even the most determined zoöphilists have not turned vegetarians, and the only one we have

[1] Heart and Science. A Story of the Present Time. By Wilkie Collins.

heard of who says she will refuse to profit in any way by knowledge gained in ways so abominable—we mean Miss Cobbe—has not, so far as is known, attempted to live up to such an absurd quibble as this, and forego therefore her daily beef or mutton.

A practitioner is next presented to us who wishes an opportunity to expose the "false pretences under which English physiologists practise their cruelties." He writes, seeking this chance, a letter to a publisher, in which he is foolish enough to say that there is no "proof that the effect of a poison on an animal may be trusted to inform us with certainty of the effect of the same poison on a man." He instances the insusceptibility of pigeons to morphia. We thought that it had long since been sufficiently demonstrated that the different actions of drugs (we do not know why he speaks only of *poisons*) on man and on animals are matters of degree, not of quality, or are dependent on the differences of habit or of organization. If enough opium be given a pigeon, it dies; it has no immunity from the poison; and it dies with the same symptoms that a man opium-poisoned exhibits. He goes on to speak of the "infernal cruelty" of those celebrated "baking-alive" experiments, and says that they have given us nothing new in the treatment of scarlet fever. Perhaps they have not; but they have greatly added to our knowledge of how fever kills, and what its processes are. With accurate knowledge of how a disease or a poison kills, we stand no longer in the position of the blind man with a club, sometimes striking the disease and sometimes the patient, who represents the physician in D'Alembert's fable.

This wise "practitioner" also insists that it is a pretence that our practice of surgery has ever been improved by experiments on animals. Doubtless he had been educated for a novelist, not for a physician, and had never heard of Sir Astley Cooper's experiments on the formation of bone, or of Cohnheim's on inflammation, or of Hunter's or Heidenhain's on the surgery of tendons, or of how Simpson proved the usefulness of chloroform.

Mr. Collins's doctors are all equally absurd and impossible, unless it be the happily named Mr. Null, who is an excellent portrait of a respectable, stupid, old-fogy, routine practitioner, who might be expected to say, being forty years or so behind with his facts, that nothing had ever come of vivisection.

Were it not for the general public interest in what is called vivisection, this book would call for no notice from us. It is weak, the story is silly, the plot is wanting, the arguments are absurd, and each one of the characters is more impossible than the last. Mr. Collins is well fitted as a special pleader in one way. It is easy to talk on almost any subject if one be not hampered by information. Finally, we repeat it as our belief, and we think it is that of an enormous majority of the medical profession, that scarcely ever has a decided advance been made in medical practice, in surgery, in physiology, in pathology, or in therapeutics which has not either directly proceeded from, or been greatly aided by, experiments on animals.

Much, moreover, as this mode of research has increased our knowledge of curative medicine, still more vast seems the less-explored field which is daily spreading further, for the investigation of what we may do in *preventive* medicine. Naturally it is a matter in which we cannot balance accurately the accounts or formulate the good done, and say, "so much pain inflicted on rabbits = minus;—so much good done mankind = plus." Preventive medicine owes its existence and all its progress to such experiments. We are but just beginning its study, and endless possibilities of good open before us. To make these possibilities probabilities, and these probbilities finally certainties there are are but two ways: one is by the commercial form of experiment on man, which has been tried and found very fatal, many hundreds of years now; the other is by a dozen or so of carefully planned and watched experiments on a few rabbits or guinea-pigs, and then the application of the knowledge thus gained. Let the zoöphilists say, if they dare, they consider the commercial experiment on thousands of men justifiable, and the scientific one on a few rabbits unjustifiable. We shall continue to prefer the latter, and so will every reasoning mind.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 4, 1883.

THE PRESIDENT, DR. WILLIAM J. MORTON, IN THE CHAIR.

DR. GEORGE W. JACOBY read a paper upon

NEUROTIC AFFECTIONS ACCOMPANYING JOINT LESIONS.

The history of the subject goes back as far as Hippocrates, by whom it is mentioned. John Hunter was the next to take any note of it, and it is with him that originated the sympathetic theory. Malgaigne, 1826, and within the last ten years, Weir Mitchell, Duchenne, Verneuil, Sir James Paget, and Charcot and his pupils, comprise the list of names that have cast light upon the subject. The experiments of Valtat show conclusively that as a result of injury to the articular, or even to the periarticular tissues, produced by irritant injections, the muscles of the entire limb, but more particularly of the extensors of the joint, become atrophied. The result of the experiment given in the paper, as shown by the autopsy, is that the extremity which was experimented upon lost eighty grammes in weight in twelve days, and that each and every muscle separately weighed less than its corresponding fellow of the left side.

The affections which most frequently follow joint disorders, are paralysis and atrophy of the muscles, and hyperplasia of the subcutaneous connective tissues. More uncommon are anæsthesia, hyperæsthesia, analgesia, hyperalgesia, and neuralgia.

Three groups of nerve functions are implicated, motility, sensation, and nutrition. The symptoms are, after the joint lesion, changes in the appearance of the limb. The extensor muscles are generally involved.

There is a change in the electrical reaction of the muscles, their contractile power is diminished and finally lost. There is no reaction of nerve degeneration, no reversion of the normal contraction formula. This is also most noticeable in the extensors. The paralysis may appear as early as twenty-four hours after the accident—may also appear very late. The hypertrophy

of subcutaneous connective tissue seems to stand in a direct ratio to the atrophy of muscular substance. The atrophy is ascending and progressive; contracture is rare. The disorders of sensation are early symptoms, and differential diagnosis between these affections and progressive muscular atrophy may become difficult.

The conclusions which I am entitled to draw from the notes of thirty cases are: First, that in all cases, except those involving the ankle- or wrist-joint, the muscles affected were the extensors of the diseased articulation. Second, that in those cases which involve the ankle- or wrist-joint, the affection is descending instead of ascending, and that the extensors are not affected to any greater extent than the other muscles. Third, that in cases of arthritis of any of the joints of the fingers, the interossei muscles suffered first and most.

The cases which present particular interest are the following.

Case I.—Mrs. L., aged twenty-four. While walking, slipped and fell, striking her right knee. The joint rapidly increased in size, and was very painful. The following day it was very much enlarged, the patella pushed forward, and fluctuation was distinctly noticeable. The joint affection improved rapidly, but upon the seventh day a distinct paralysis was noticeable. The movement of flexion of the leg upon the thigh was easily executed, but that of extension was performed with great difficulty. Patient could only by the strongest effort produce any contraction of the triceps cruris. As the effusion became absorbed, the paralysis increased, and at the end of three weeks it was impossible for her to extend the leg at all. Atrophy was now well marked, showing a difference of three centimetres in favor of the healthy limb. The gluteal muscles were also involved. The electro-contractility of the muscles was decreased to both currents.

Case II.—This case shows how soon after the injury paralysis and atrophy may ensue. Patient, a laborer, aged thirty-four, was struck upon the left knee, on a Friday afternoon. He applied ice to the joint; the swelling went down. I saw him upon the following Monday, seventy-two hours after the injury, and then a distinct paralysis of the triceps cruris was noticeable, and atrophy was distinguishable upon the following Friday.

Case III.—By this case may be seen how entirely disproportionate the effect may be to the cause. Patient, L. H., merchant, aged thirty. While walking, his left ankle-joint turned, the outer margin resting upon the ground. Notwithstanding severe pain, he continued his walk; used the joint for several hours. When he examined his foot he did not notice any change in the appearance, but it was painful on pressure. After two months, he noticed a slight weakness in the injured leg, which was particularly observable upon going down stairs. Four months after the accident I saw him. His condition was then as follows: His foot hangs with the toes pointing downward, and cannot be brought to a right angle with the leg. He walks upon his toes, and does not bring his heel to the ground. The toes may be easily raised, but they fall back again by their own weight. The interossei of the foot are atrophied. The peroneal muscles, the muscles of the thigh, are also involved. The gluteus maximus is evidently considerably atrophied, for a large depression takes the place of its former prominence. Added to this, severe neuralgia of the sciatic and peroneal nerves rendered a condition almost unendurable.

The pathogenesis of the affection is still a disputed one. The sympathetic theory of Hunter; the pressure theory of various writers; the theory of functional inertia; then that of Vulpian, which is reflex; and finally those of Decosse and Charcot, are all incapable of satisfactorily explaining all of the cases.

The treatment, in order to be successful, must be varied, and adapted to each special case. The chief agents at our disposal are electricity, massage, mechanotherapy, and hydrotherapy in the form of hot and cold douches. Massage, in very many cases, seems to deserve preference to the electrical currents. The effects producible by massage are: (1) The diffusion of any articular effusion. (2) The comminution of vegetation. (3) The loosening and destruction of adhesion. (4) Increase of circulation. (5) Stimulation of muscular fibres.

In fact, all the agents above mentioned seem to act similarly by stimulating the nutrition of the affected muscles, by increasing the flow of blood to the parts and perhaps thus causing a reflex excitability of the motor tracts.

DR. CHARLES FAYETTE TAYLOR said: This is a subject with which I have considerable familiarity, as all persons who are extensively engaged in the treatment of joint affections must have, but it is too large even to touch upon, in many of its aspects, in the limited time at my disposal to-night, even if I had prepared myself for such a discussion by having previous intimation of the direction it would take. I should prefer to have the subject arranged before speaking of it, especially as I shall be obliged to differ from the essayist, both as to the pathology and treatment of the neurotic disturbances attending or following joint diseases of the character which he has set forth in the paper. In regard to the pathogenesis, I do not think it is necessary to adopt any peculiar theory, or to assume that even any special deviation from the ordinary course of nerve function takes place, in order to account for all the facts observed in these cases. The difference is one of degree only. A person is attacked with inflammation of the knee-joint, for instance. This is rapidly followed by diminished size of the muscles controlling the action of that joint, with diminished and sometimes even with entire loss of muscular action. But loss of muscular action is by no means evidence of loss of muscular power. The nerve-centres are unquestionably affected; but, most of all, the cerebral nerve-centres are the seat of the greatest disturbance. No theory can be adequate which leaves the cerebral nerve-centres out of the account, and the consequent mental element which plays, in my opinion, so important a part in these cases. The simple loss of muscular action, consequent on an attack of inflammation of the knee-joint, is sufficient to account for an immediate diminution of the size of the muscles whose freedom is curtailed. This is the certain result from mechanical restraint alone. But if, besides the mechanical restraint of position or retaining apparatus, there is added the mental restraint of fear, the difference in the rate and amount of muscular atrophy is enormously increased. Mental restraint acts similarly to an Esmarch's bandage; it squeezes the very life out of a muscle. As a very simple proof of the remarkable effect of mental restraint in causing muscular atrophy,

let me mention those frequent instances accompanying disease of the hip-joint. These cases often apply with limbs attenuated to the last degree. That a large portion of the muscular attenuation, accompanying somewhat long-standing hip-joint disease, is due to the mental restraint of motion, which might cause suffering, is proved by the fact that the application of proper mechanical protection, by which the mind is relieved of the fear of pain, is followed by immediate increase of muscular growth. This is so common and well known a fact that advantage is constantly taken of it, in the management of cases. My observation of the effects, on the muscles, of joint diseases must amount to some thousands of cases, and I never saw a case of atrophy which, in my opinion, could not be perfectly explained by non-use and mental restraint.

In regard to the therapeutics of muscular atrophy and loss of action following joint disease, I fear I must differ from the essayist quite as widely as in its pathogenesis. So far as the muscular wasting has been caused by non-use during the progress of the arthritis, it is sufficient to set them to work again after the inflammation has subsided. And I may say, in passing, that muscles stubbornly refuse to act, or, if forced to act, they as stubbornly refuse to develop during the progress of an arthritis. You must wait until the joint is well before you can expect the muscles to act readily enough, after there is no longer any joint affection, except for the restraint which is often maintained for a long time by mental impressions formed during the progress of the arthritis. It is astonishing to notice how deep and lasting the impressions made on the cerebral nerve-centres may sometimes be. Whatever the treatment adopted, I do not believe it can be of any direct service as long as there continues a mental restraint over the muscles, and it is equally true that whatever will remove such mental restraint will cure the atrophy. So important do we, in our practice, consider the mental influence over the muscles attending and following joint diseases, that we take special pains to get and to keep the direction of that influence for the very purpose of hastening the recovery of the muscular power after curing the joint disease. But the object of treatment should be to divert the mind from the affected member rather than to keep up attention to it by local treatment. It is true that massage will sometimes seem to do much good to the atrophied muscles; but this is apparent and indirect rather than real and direct. Massage has elements of mental diversion and control, which may be properly and usefully employed. But with a large experience in its use, I am free to say that I think it is very much over-estimated as a direct therapeutic agency. Its direct effect on the muscles is very slight, and what there is, is not exercise. Exercise involves nerve action as the initial force. Massage merely assumes to promote the forward displacement of a certain small portion of the tissue fluids. But such propulsion of the fluids contained in the soft parts, even if effected, is not exercise nor a rational substitute for exercise. Only by the legitimate use of the nerve-centres, especially of the cerebral nerve-centres, can there be any action deserving the name of exercise. To regulate such nerve-centre function when disturbed by the strong impressions made by joint inflammation, is the indication presented in the cases under discussion. In most cases time alone is sufficient. In others any means which effects a diversion of attention, whether done to the affected member or at a distance from it (which is the safer plan), will effect a cure. Incidentally, massage, electricity, the manipulations of the so-called "bone-setters," as well as the "animal magnetism" of the more arrant quacks, all appear to produce wonderful results in a certain number of cases. The results are real, but are not produced through any direct effect on the parts, but through the incidental impressions made on the cerebral nerve-centres—that is, on the mind. The worst of it is that in a large number of these cases direct treatment to the part affected by the mental restraint tends to increase the mental impression and to postpone indefinitely that unrestrained action of the muscles by which alone they can regain their power. The most difficult cases within my experience have been those who have had their attention to the affected member kept up by too much local treatment after the joint inflammation had passed away.

DR. L. WEBER had seen some cases of muscular atrophy following joint disease, and remembered one in particular which may be of interest to the Society.

Mr. J. W., age 32, merchant, of nervous temperament, but strong and active, made a tour through Switzerland in the summer of 1870. Being a good pedestrian, he travelled mostly on foot, but after a severe Alpine tramp in the upper Engadin, he was taken with synovitis of the right knee-joint. When the effusion had passed away, the extensor muscle above the knee had wasted considerably; the patient was unable to walk, and reached New York with difficulty. On examination, the joint was found to be in good order again, but the atrophy of the extensor muscle was still very marked, and the patient, by the support of a cane, walked, but not without difficulty. A four weeks' course of faradization made no appreciable change; and although he was assured that he would regain the use of his limb completely in the course of time, he was not satisfied, but grew despondent, and finally left for Europe to consult Prof. Erb. The latter told him the paralysis was not in his limb, but in his mind; that he should go about, and exercise, and live well, and he would soon regain the full use of his muscles. He followed the Doctor's advice, and returned to New York early in the spring of 1880 in perfect health. As to the pathogenesis of the disorder, the Doctor believed that the muscular paresis and atrophy in the case reported, and in others of a like manner, are of reflex origin, and that functional disturbances of motor centres in the brain, and not in the spine, are probably the cause of the trouble.

Of massage and its effect in such cases, as reported by the author of the paper, he had no personal experience, but had seen excellent results from its proper application in subacute joint diseases, muscular rheumatism, and bad sprains.

DR. E. C. WENDT said that the paper had brought out several points of interest, especially as regarded etiology, symptoms, and the hopefulness of treatment. He was sorry to find, however, that the reader had nothing new to offer in explanation of the pathogenesis of these conditions. Admitting the correctness of Sappey's views concerning the richness in nerves of the articular and periarticular tissues, it certainly seems thoroughly puzzling why acute polyarticular rheumatism

was not more frequently followed by just such accidents as Dr. Jacoby has described. Again, those more chronic joint manifestations dependent upon the gouty diathesis, where profound structural alterations were frequently observed, only quite exceptionally led to atrophy, paralysis, and to other neurotic disturbances alluded to.

Upon these points he was sorry to find that the paper under discussion left us as much in the dark, as we had been before.

With regard to massage, although his experience was limited, it was yet sufficient fully to convince him of its utility in certain cases. Of course there is massage and massage, but when properly and systematically applied, it is useless to dispute its beneficial action. The combined experience of a large number of competent men placed its usefulness beyond the pale of doubt.

DR. HEITZMAN said: When I was a student in Vienna, a girl, twenty-five years of age, fell down stairs and acquired serous gonitis, after which she was paralyzed and confined to her bed for five years. She was sent to a water-cure. A physician there urged her to walk, in order to enable him to judge of the degree of the disease, but she began crying, and said she was unable. She went home in despair; her sister asked her to make at least an effort to walk. After considerable urging she got out of bed and walked. This illustrates that mental influence has much to do with these affections.

I would call the attention of Dr. Jacoby to an article by Dr. Nicoladoni, published in 1871, in the *Wien. med. Jahrbücher*. I have seen his specimens with the nerves brought out by the use of chloride of gold, and from my observation I am convinced that these terminal nerve-fibres are not stable and unchangeable formations, but that, on the contrary, new nerve-fibres may form at any time of life from the living matter present in all tissues. I am thoroughly convinced that nerves may disappear and appear, according to certain physiological necessities, certain physical conditions of the body, such, for instance, as the result of exercise.

In an inflammation of a joint, the synovial and capsular wall being the seat of pathological changes of the breaking down of the tissue, certain nerve-fibres of the sensitive sphere will be within its range, and we should know that a certain number of them perish altogether.

Dr. Jacoby, to-night, did not give a theory of his own, but he quoted various authors. It certainly was the best plan for him to pursue, as so very little is known, even in our day, about nervous action. We know that by the inflammatory destruction of a number of sensitive nerve-fibres in the capsule of the joint, at once three spheres are involved: the motor, for there is paresis or paralysis; the sensory, for there is pain; and the vasomotor, or trophic, for there is emaciation. So far as my insight goes, I am convinced that the living matter in a vehicular arrangement produces the gray matter and all essential portions of nerves, including the axis-cylinder. This fact is thoroughly acknowledged by Prof. Stricker, at Vienna. There may be loss of living matter of certain nerves in consequence of inflammation and loss of contractil[illegible] with impaired conduction towards the centre. We then have comparative rest in a limited portion of the spinal cord, or even the brain, for the reticulum of living matter is set at rest for a time, without there being a material change in the living matter of the gray substance and ganglionic elements.

If massage will reëstablish the activity of muscles, we are prepared to understand that the field in the spinal cord, before out of action, may at once be brought in motion, and the motion communicated at once to the motor ganglia and all the sympathetic centres, which are situated along the spinal cord, as physiologists agree upon. The nervous action may for a certain time be impaired or dulled, because the reticulum of living matter is in comparative rest, lacking an impulse from without. So soon as such an impulse is carried to the resting portion, either by mental action, energetic will, or by mechanical shock, such as is done in massage, or in any other way, the contraction of the living reticulum is induced, and the normal condition reëstablished. Neither the assumption of centripetal neuritis nor the theory of reflex action can explain the phenomena observed after the inflammation of articulation and their sometimes speedy cure.

DR. HENRY LING TAYLOR said: I can contribute a case showing the beneficial effect of the use of the body-battery. A woman, under the care of Dr. J. West Roosevelt, at the Roosevelt Hospital Dispensary, of middle age and neurotic personal and family history, presented, among other symptoms, that of a prickling sensation down right arm and in right hand. There was no joint trouble. Dr. Roosevelt and I regarded it as one of the neurotic disturbances incident to a person of her temperament. The body-battery was tried for its psychical effect, and the woman returned in two days with the abnormal sensations gone. The symptoms had lasted a considerable time. The same treatment was applied to the hand without effect during the week, and she has since been under observation. I regard the result in this case as entirely due to mental influence.

Before concluding my remarks, I wish to speak of an interesting class of cases, alluded to by Dr. Gibney—the pseudarthroses. We have in these cases nearly or quite all the symptoms enumerated by Dr. Jacoby in his paper; atrophy, hyperæsthesia, or anæsthesia, etc., following mental restraint, there being no affections of the joints. I regard the trouble as functional, and seated mainly in the brain, and not in the spinal cord, as Dr. Gibney believes, if I understand him. Almost anything calculated to make a profound impression on the higher nerve-centres will often prove curative in these cases. This is, in my opinion, one of the most important effects of massage.

I have in mind three cases of ankle trouble following sprains, seen three to five months after injury. The acute symptoms had subsided; but pain, tenderness, and such impaired function as to cause limping persisted. These patients had been treated with supports, etc., for several months. Physical examination showed no local trouble not readily explained by mental inhibition. There had been recovery from the sprain without a corresponding readjustment of the nerve-centres to the new condition.

The patients were perfectly and rapidly cured by purely psychical treatment. I do do not doubt that massage often accomplishes the same result, through its psychical effects, in similar cases, but it is an empirical method as generally employed.

DR. GARRIGUES said: What little experience I have had with massage is in its favor, but that is almost

nothing compared with that of Dr. Taylor. Nevertheless, I have used massage for ten or twelve years. I became acquainted with it when it was quite new, and have found it most excellent for secondary conditions, and for treatment to which Dr. Jacoby alludes.

DR. MORTON said a few words upon the subject of the continuous body-battery and its use; the battery consists of a simple pair of elements. He recalled a case in which he used this with good effect. A gentleman came to him with chronic arthritis; associated with it was paralysis of the extensor group of muscles; the foot was dropped, and the toe dragged. He said no form of electricity that he had tried had done him any good. He gave him a battery which he could wear all the time, which consisted of pieces of silver and zinc, connected by copper wire. The zinc was shifted about upon different parts of the body; a constant current was kept up, which could be tested at any time with ordinary litmus paper. While under alkaline treatment the battery worked with better results, the excretions being saline. This battery is also useful in the treatment of chronic ulcers; the granulations formed will be found much more healthy. It is also beneficial in chronic eczema.

DR. GIBNEY said that at times it is very difficult to determine whether the atrophy precedes or follows joint disease. It is his opinion that it is more frequently the accompaniment of epiphysial disease than joint disease proper. And he wished to emphasize the fact—for a fact it was according to his observations—that the majority of grave lesions about joints in childhood was epiphysial; in other words, a chronic epiphysitis. Synovial disease he believed to be rare. If one examined a hip, for instance, said to be the subject of disease, marked atrophy is usually found in the thigh and calf muscles long before any pronounced joint symptoms are presented. The atrophy, he further stated, is confined to the muscles, and not to the bony tissue; for it is a rule that in chronic epiphysitis, about the knee for instance, that the epiphysis is actually elongated. He, in common with many other orthopædists, has long since regarded acute atrophy as one of the most constant signs of chronic articular ostitis; and he believed the atrophy to be purely reflex, and not the result of disease, or of the pressure from apparatus or bandages.

One argument brought against mechanical treatment, viz., that atrophy was produced, is fallacious. The clinical history of these bone lesions proves this conclusively. He was not sure whether chronic synovitis induced atrophy; but he was very positive in stating that in acute synovitis atrophy was rather the exception than the rule.

A class of cases presented certain neuroses which were very valuable in excluding bone or joint disease. These are known as spinal pseudo-arthropthy; and known furthermore as neurosis of the joint, neuro-mimesis, hysterical joints, Brodie joints, etc. The neuroses referred to were neuralgia, hyperæsthesia, and anæsthesia, but rarely any atrophy. He believed that they had their origin in the spinal cord and in the meninges; and the readiness with which they responded to spinal treatment confirmed him in his belief. Furthermore, the neuralgia of chronic ostitis of the hip is well known, and the knee-branch of the obturator nerve is affected early, and often very late, in the disease; although this is denied by some writers, and especially a recent writer, Dr. Clippingdale.

In some of the most advanced cases of caries of the hip, this obturator neuralgia is very distressing. Very frequently the sciatic nerve is involved, and in some cases, one especially narrated in a young lady with old disease at the hip, the sciatica was most distressing and yielded very poorly to drugs and electricity. The question of paralysis and degenerative nerve changes being sequences of chronic arthritis was one of which he did did not feel fully convinced.

He referred to a case of chronic arthritis of the knee, in an old woman who had paralysis of most of the muscles of the thigh and leg, and it was thought by some who saw the case that the paralysis was dependent on the joint lesions, but the proof was not by any means conclusive.

DR. JACOBY, in concluding the discussion, said: The first point to which I desire to reply is that brought forward by Dr. Taylor. He said that he believed these nervous changes, particularly the paralysis and atrophy, were produced by psychical or mental influence, and that they might be relieved by attention to this point. I am at considerable variance with him as regards the effect that mental influence has in the production of these disturbances. I, for my part, cannot understand how mental uneasiness can produce an atrophy, which is easily diagnosed by the tape, of a certain muscle, and that in the short time of three days. But, as the Doctor has promised us a paper upon this subject, perhaps that will succeed in convincing me.

As regards the opposition which the massage treatment has received, I expected it would receive more. Massage has, especially in the United States, been very much in the hands of non-professional men, and consequently has been greatly abused and misapplied. But I hardly think there can be any question as to its efficacy in suitable cases, when properly applied.

The theory advanced by Dr. Heitzman, is very similar to that of Prof. Charcot, who, as I mentioned in the paper, believes that certain parts of the cord are in a state of inertia or stupor.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

Stated Meeting, December 5, 1883.

THE PRESIDENT, ALFRED STILLE, M.D., IN THE CHAIR.

DR. JOHN H. PACKARD presented the following report of a

CASE OF ABDOMINAL TUMOR, SOMEWHAT RESEMBLING PREGNANCY, IN A YOUNG MARRIED WOMAN.

Mrs. G., æt. 21, a very delicate-looking woman, consulted him July 21st in regard to a slight and uniform abdominal enlargement, which had been first noticed by her shortly after her marriage, about three months previously, and had been gradually and steadily increasing. She menstruated regularly every month, and had had no nausea. Neither the breasts nor the nipples showed any change from the virgin state. There was no tenderness at any point in the abdomen, and the appearance and feel of the swelling were very much such as would be presented in the early stages of pregnancy. The os uteri was soft, and the cervix was of some length

but there was a bulging above, as if the uterus contained a mass partly solid and partly liquid. He did not think it right to introduce a sound, as, in spite of the absence of rational signs, the presumption seemed to be in favor of pregnancy. Against this one fact seemed to militate, viz., that she rather lost than gained flesh. I declined to express any opinion as to the character of the swelling, but told the husband that my hope was that the case would prove to be one of pregnancy, as it was likely otherwise to be very grave.

The swelling continued to progress steadily, and on Sept. 13th she presented the appearance of being at about the middle of the fifth month of gestation. The hypogastric pain troubled her greatly, and was only allayed for a very short time after each application of chloroform liniment.

Dr. Ellwood Wilson saw her in consultation on Sept. 15th. In the forty-eight hours between the previous visit and this one, a very marked change had taken place. The abdomen had become greatly enlarged, its walls forming one curve from the ensiform cartilage to the pubes; there was very decided fluctuation, and percussion showed an area of dulness which was attributed by Dr. Wilson to the existence of a cystic tumor connected either with the Fallopian tube, or with the broad ligament. A sound was introduced into the uterus, the cavity of which was found to be unoccupied. On the 17th, more than a gallon of ropy, yellow liquid, somewhat deeply tinged with blood, was removed by aspiration; the flow then ceased, and the end of the canula encountered a solid substance, apparently a septum of considerable thickness. Upon the withdrawal of the instrument, a fresh flow took place, the liquid spouting out from the orifice to a distance of several inches. When this subsided, the abdomen, which was much less tense, was covered with raw cotton, and a bandage carefully and firmly applied.

In the evening the temperature rose to 103.5°, but before morning it fell to about 100°. The wound in the morning was found closed. The following evening the temperature again rose to 103.5°, but subsided again before morning, and was not thereafter above 99°. Yet her condition was unsatisfactory; her face was much pinched and anxious; she had very little appetite; at times her mind wandered slightly, and she slept but little. Vomiting occurred frequently, and she was seldom free from nausea. Her bowels acted regularly; her urine was free, and normal in every respect. Her pulse varied, but was generally from 110 to 120.

A portion of the liquid was submitted to Dr. H. F. Formad for examination, and his report, which was not received until some time after the case had terminated, was: "I think it very doubtful that it comes from an ovarian cyst, the fluid showing very little epithelium, and very few of the ovarian cells of Drysdale."

Sept. 23d her condition was very much more favorable; her mind was composed and even cheerful, her pulse and temperature good. Some food had been taken and retained.

On the 24th her state was much the same, and it was thought proper to entertain the idea of an operation for the removal of the supposed ovarian tumor. In the afternoon, Dr. Agnew saw her with Dr. Wilson and myself, and it was decided that the attempt should be made on the following day.

Accordingly, on the 25th, the abdomen was opened by an incision in the median line. After dividing the wall Dr. Packard came to what seemed to be a cyst, and passed in an ovariotomy trocar, when a very free evacuation of liquid, straw-colored and ropy, but clear, took place. It was now apparent that the liquid was contained in the peritoneal cavity, and that there was a large solid mass lying among the intestines. This tumor was soft and doughy, like a placenta; it seemed to belong to the mesentery, since although somewhat movable, it was firmly attached to the posterior wall of the abdomen, rather high up. The surface of the mass having been slightly lacerated, there was somewhat free bleeding, which was checked with some difficulty by ligation with carbolized catgut, and by the application of a cautery-iron. The wound was now closed with two large pins and a ligature cast around them, and with metallic sutures; a sheet of raw cotton was applied over the whole belly, and secured by a bandage. The patient rallied considerably, and after the effects of the ether had passed off, became quite sensible; but she soon began to sink, and died on the 27th, about forty-eight hours after the operation.

No autopsy could be obtained, so that the exact nature and connections of the tumor must remain matters of conjecture.

The notable points in the case now detailed seem to be the occurrence of a solid tumor, probably of malignant character, and apparently connected with the mesentery, in a young woman recently married; its resemblance in its physical appearances to the pregnant womb; the very sudden change that took place by a fresh effusion into the peritoneal cavity, and the obscurity which even then existed as to the real nature of the case. Even with the most accurate diagnosis, effective treatment would have been out of the question, and Dr. Packard cannot but think that his suspicion of pregnancy, erroneous as it proved to be, really prolonged the patient's life, which would have been almost necessarily sacrificed by earlier interference.

RHODE ISLAND MEDICAL SOCIETY.

Semi-annual Meeting held at Providence, Dec. 20, 1883.

THE Society met at 10 A.M. THE PRESIDENT, DR. JOB. KENYON, in the Chair.

DR. S. S. KEENE reported for the

BOARD OF CENSORS,

that Clarence Miles Godding, M.D., and Philip K. Taylor, M.D., having passed a satisfactory examination, were recommended for Fellowship. The two applicants were subsequently elected by unanimous votes.

The report of the committee on the subject of

ABOLISHING THE CORONER LAW

in Rhode Island, and substituting for it the office of medical examiner, was presented by DR. LLOYD MORTON, of Pawtucket.

The Committee recommended that another committee be appointed to see that the draft of a law, which the committee offered, is properly presented to the general Assembly at its coming session, and to adopt such

measures as may seem judicious and necessary to secure its passage.

The bill, as framed, provides that the Governor appoint in all twenty-two *medical men*, to serve as medical examiners in the respective districts into which the State is to be divided for this purpose. The term of service to be six years, unless removed for cause. A bond of two thousand dollars to be required. The fee for viewing a body is four dollars; for the same with autopsy, thirty dollars. Travelling fees, to go and return, at the rate of thirty cents a mile. Examinations to be made of such deaths as are suspected to be due to violence or crime. If, in the opinion of the medical examiner, death resulted from natural causes, the body is to be simply delivered to the friends for burial; but if a crime has been committed, the case then goes into the charge of the judiciary. In the many sections of the draft, careful provision is made relative to the matter of autopsies, chemical analysis, the subpœna of witnesses, etc.

DR. ARIEL BALLOU made a few explanatory remarks, after which it was voted to accept the report of the committee.

DR. MORTON explained further that by the new draft the medical examiner would have no *legal* authority whatever.

DR. BALLOU expressed his belief that the old English coroner law was the best; but owing to the poor quality of men now serving as coroners, we have been mortified at its working at the present time. Men are needed who are conversant with criminal law and able to ferret out the perpetrators of crime. The draft of a law now submitted separates the medical from the judiciary part of the investigation, the function of the medical examiner being simply to develop the evidence.

It was then voted to add the name of the President, Dr. Kenyon, to the committee already constitued, and that, thus augmented, the same committee be empowered to present the draft before the general Assembly.

DR. D. H. BATCHELDER then read a long paper on the

PATHOLOGY AND TREATMENT OF INFLAMMATION.

He thought the real, primary *cause* of the phenomenon called inflammation was as yet unknown. Also that in case of active inflammation of the brain, heart, or lungs, venesection was the most rational and best treatment. He cited one case in point: he was called in consultation to see a man suffering intensely from acute, primary carditis. The patient's agony was extreme, and had been for hours. The attending physician had tried all the reputed cardiac sedatives and innumerable external applications, with no avail, and death seemed imminent. Dr. Batchelder advised venesection, and at once took ℥xxx of blood from the man's arm. No relief followed for half an hour, when he took ℥xx more; still no relief; and he bled him again to the extent of ℥xl, when the patient looked up and said he felt better. In all, ninety ounces of blood were taken. The man recovered.

DR. H. TERRY reported

A CASE OF TUBAL PREGNANCY

that occurred in the practice of Dr. A. D. Weeks, of Providence.

The woman, aged thirty-two years, had been married two years. She had one child eleven months ago, the labor then being an unusually easy one.

Believing herself to be two months pregnant for the second time, and in good condition, so far as she knew, she was seized at four P.M. with dull pain in the *right* ovarian region, with vomiting and faintness, which lasted half an hour. The dull pain continued, but she was about the house until seven P.M., when she fell into a state of collapse, with imperceptible pulse, shallow respiration, but clear intellect, which continued until death took place at eleven P.M. An autopsy found the abdominal cavity filled with partially clotted blood, the right Fallopian tube ruptured, and the fœtal head engaged in the torn orifice, of which the margins were very thin. Chorionic villi and a partially developed placenta were found in the uterine cavity. Only *one* corpus luteum was found, and that was in the *left* ovary.

On being asked to explain the presence of a single corpus luteum in the *left* ovary, whereas the fœtus had developed on the opposite side, Dr. Terry replied that one of three things *must* be true—either (1) the fimbriæ of the right Fallopian tube grasped an ovum from the *left* ovary, or (2) an ovum from that ovary crossed over to the *right* Fallopian tube, or else (3) the established theory regarding the connection between ovulation and impregnation must be incorrect.

ANEURISM OF THE THORACIC AORTA.

DR. CHARLES O'LEARY reported the case of a man, thirty-four years old, who died on the 14th inst. About four years ago he began to complain of severe pain in his back, and this symptom continued up to the time of his death. Last summer strong pulsation was discovered in the left lumbar region, but no bruit was audible. The man was examined by Dr. Alonzo Clark, of New York, who made no positive diagnosis, but was of the opinion that the pulsation was due to the cardiac impulse being transmitted through some solid medium, the nature of which was undetermined. Several other physicians concurred in this opinion. At times the patient suffered agonizing pain, requiring the use of large amounts of morphia hypodermically. Four days before his death he began to have pain in the left knee and along the course of the sciatic nerve. His death was finally caused by a convulsion. An autopsy revealed an aneurismal sac, branching off from the left side of the thoracic aorta just above the diaphragm and extending down along the course of the psoas muscle to the lower lumbar region. This sac was full of clotted blood, and had caused almost complete atrophy of the psoas muscle, and extensive erosion of the eleventh and twelfth dorsal and first, second, and third lumbar vertebræ.

THE LIBRARY.

DR. G. W. PORTER announced that arrangements would soon be completed for keeping the Medical Library open from 2 to 6 P.M., in addition to the plan now in vogue of a single hour from 12 to 1 P.M. Also that a telephone had been placed in the library.

The Chair then named the following

DELEGATES

to the meetings of other State medical societies:

Massachusetts.—Drs. Brown and Ham.

Connecticut.—Drs. F. B. Smith and Levarts.

New Hampshire.—Drs. Fisher and Ballou.
Vermont.—Drs. Leonard and Luew.
New York.—Drs. Baker and Caswell.
Maine.—Drs. Porter and D. O. King.

The President then invited the Fellows to a lunch at Ardoene's. Adjourned.

MEDICO-CHIRURGICAL SOCIETY OF MONTREAL.

Stated Meeting, December 14, 1883.

THE PRESIDENT, DR. T. A. RODGER, IN THE CHAIR.

SYPHILITIC CARIES OF INNER TABLE OF SKULL; GREAT THICKENING OF CALVARIA; COMPRESSION AND DEFORMITY OF THE BRAIN.

DR. OSLER exhibited the skull-cap and brain. The patient, a woman, aged thirty-five, had died in the General Hospital, under the care of Dr. Godfrey. She had been an inmate of the institution many times during the past six years, with various manifestations of syphilis: had extensive necrosis of right tibia, and for fully two years had had a small open sore on right parietal bone. In November she was admitted with severe headache and debility. The headaches had troubled her for some years, were nocturnal, but latterly constant, and chiefly on the right side. There was a discharge from the sore over the parietal bone, and a probe could be passed through a small sinus which led beneath the dura mater. There was abundant highly albuminous urine, and amyloid disease of the kidneys was suspected. She was rather a dull, stupid woman, but during her last stay in hospital the intellect was clear, and there was no motor disturbance. A few days before her death the nurse noticed her to be unusually dull, yet irritable when spoken to. The right tibia had healed with extensive hyperostosis and deformity.

The external surface of the skull-cap was smooth, and on the right side, close to the coronal suture, there was a small sinus through which a Bowman's probe could be passed. On removing the calvaria, which was moderately thickened in the supra-orbital regions, a quantity of thick pus escaped. The dura mater was thickened, and strongly adherent posteriorly. The internal surface was smooth, and did not present any adhesions. As shown in the specimen, the disease is confined to the contiguous surfaces of skull and dura over the frontal and part of the parietal regions. The inner aspect of the bone in these parts is rough and carious, having an eroded, worm-eaten appearance, and covered in places with granulations; and towards the parietal bone, firm, solid fibrous masses unite it to the dura. The upper half of the frontal and the greater part of the parietal bones are thickened, measuring from two to three centimetres, and are exceedingly dense. The outer surface of the dura mater shows numerous soft granulations springing from solid fibrous tissue. The falx in its anterior half is thickened, and the longitudinal sinus is in this part obliterated. The brain showed no trace of coarse disease; the arachnoid was a little opaque, but the pia mater was normal. The hemispheres were curiously deformed from the pressure to which they had been subjected by the thickened bone and dura, and the pus between them. They are wedge-shaped; the base is at the occipital lobes, where the greatest vertical height is eight centimetres, and the apex is at the orbital margin of the frontal lobes, where the height is only two and a half centimetres. This curious deformity has been brought about slowly, and illustrates the degree of pressure to which the brain may be subjected, so long as it is applied gradually.

DR. HENRY HOWARD referred to the remarkable absence of cerebral symptoms in such extensive compression.

DR. OSLER also exhibited a skull, from the museum of McGill College, with syphilitic destruction of the entire right parietal and part of the frontal bones, with caries also of the inner table.

EPITHELIOMA OF TONGUE; EXCISION; ERYSIPELAS; CIRCUMSCRIBED GANGRENE OF LUNG; PERFORATION OF BRANCH OF PULMONARY ARTERY.

DR. SHEPHERD narrated the case and showed the specimen. The patient, aged forty-two, had had a portion of the tongue removed in May last for cancer, and was readmitted to the hospital early in November with recurrence in the stump and on the right tonsil and anterior pillar of fauces. On November 10, the entire organ was removed with the scissors, after ligation of the linguals. The affected tonsil and anterior pillar were also taken away. For five days the man did well; there was no fetor, and the wounds made for ligature of the linguals were healing, when, on the 15th, erysipelas appeared on the nose and spread rapidly over face, head, neck, and chest. Temperature 103° to 104°. Pulse 120. The mouth wound became sloughy. This condition persisted without special change until the 27th, when the breath became fetid and a cough developed with indications of septic trouble in the lungs. No rigors or sweats. From this time he became gradually weaker, and on December 2, died suddenly of profuse hemorrhage from the lungs. Dr. Shepherd referred to the advantage of previous ligation of the lingual in facilitating complete removal of the organ; with the scissors an almost bloodless dissection could be very readily made. At the autopsy the wound in the mouth looked in process of healing, and the cancerous masses had been entirely removed. The linguals presented thrombi at the site of ligature. There was a small pocket of pus beneath the left sterno-mastoid. The trachea and bronchi were filled with blood. The right lung presented four areas of circumscribed gangrene, the left two, each about the size of small apples. Placing the lung under water and blowing air through the pulmonary artery, bubbles escaped from one of the gangrenous regions close to the root of the lung. Dissection proved, as the specimen shows, that the hemorrhage came from a small branch of one of the main divisions of the artery, which had been opened in the necrotic process.

DR. ROBERT PALMER HOWARD spoke of the frequency with which gangrene of the lungs followed operations on the tongue and neck.

SARCOMA OF LUMBAR GLANDS; PERFORATION OF THE COLON; PERSISTENT HEMORRHAGE.

DR. SHEPHERD presented the specimen and gave the following notes: "Man, aged forty-five, large, strongly built, weighing over two hundred and fifty pounds, sent for him on July 23d, and stated that he had been seized in the night with severe pain in the back and abdomen.

The temperature was 103°, pulse 120; tongue coated; great tenderness of abdomen, with fulness in left iliac region; no vomiting; bowels had been opened several times in the night. In the evening he was worse. Temperature 104°; pulse 120; great abdominal distention with tenderness. On the 25th the temperature was normal, but the abdominal symptoms persisted, and there were diarrhœa and frequent vomiting. On the 29th he had a severe rigor, with temperature of 104°, and profuse sweating; tympanites and pain, with evidences of peritonitis. In a day or two he had another rigor, with severe vomiting and diarrhœa, and great abdominal distention. Dr. Ross saw the patient in consultation, and the conclusion arrived at was, that there was local suppuration deep in the iliac region. His condition at this time was very bad; pulse weak; vomiting incessant. With champagne and careful feeding the vomiting was checked, and he began to improve slowly, until in the early part of September he was able to move about the room. There was still fulness on deep pressure in the left iliac fossa, but the thick layer of fat prevented a satisfactory examination.

"About September 10th he began to pass a small quantity of blood—bright red—with the stools, and this increased until the daily amount was often as much as half a pint, and he became very anæmic. In the month of October he again took to bed; had severe rigors with high temperature and sweats, about every other day. At this time a tumor was made out in the hypogastric region, deep in the abdomen, fixed, solid, and not tender on pressure. Rectal examination negative. The loss of blood continued, and he got much weaker, and death took place on November 20th, after a profuse hemorrhage. The tumor had increased in size, and a week before death it seemed about the size of a child's head, and firmly fixed in the hypogastric region. The autopsy showed matting together of the coils of intestine with old peritoneal adhesions, particularly near the pelvis. The tumor was in front and a little to the left of the lumbar spine, and the sigmoid flexure was firmly united to it. The mass was readily turned out, and dissection revealed an extensive perforation of the bowel, as the specimen shows, and exposure of soft sloughing masses of the tumor. The wall of the colon was defective in an area two and a half by one and a half inches. The growth was a sarcoma of the retroperitoneal lymph glands. There were no secondary tumors, and nothing of note in the viscera. The persistent hemorrhage for over two months, had evidently come from the vessels of the exposed and sloughing part of the tumor. The repeated rigors were difficult of explanation; there evidently had been peritonitis, but whether local suppuration had occurred was not so clear, possibly it had in the process of perforation of the bowel."

DR. ROSS remarked that he had seen the case several times, and it had offered considerable difficulty in the way of diagnosis. The amount of abdominal fat prevented a satisfactory examination, and the fulness in the iliac region was thought to be possibly a focus of suppuration. Later on, when the hemorrhage occurred, and a more evident tumor could be felt, the diagnosis was made of malignant growth, and from the situation and size, probably retroperitoneal and involving the bowel.

SMALL TUMOR ON NERVE; INTENSE BRACHIAL NEURALGIA; REMOVAL, WITH CURE.

DR. SHEPHERD presented a microscopic section of a small tumor the size of a bean, which he had removed from a man's arm for painful neuralgia. The patient, a thin, nervous man, stoker by occupation, was admitted to hospital complaining of severe pain in the left arm—so bad that he could get but little rest at night. His appearance was that of a man suffering intensely. The pain was more severe at times, and was situated at the insertion of the deltoid, and from there ran down the back of the arm to the elbow. He also had numbness along the ulnar nerve. Just below the posterior fold of the axilla, internal to the brachial artery, a small nodule the size of a bean was felt, which on pressure caused agonizing pain. Dr. Bell admitted the case as one of neuroma. Dr. Shepherd had removed the growth, which was found connected with a small nerve, and closely united with the cellular tissue at the back of the artery. The man has had no pain since the removal, three days ago. The section of the tumor showed a fibrous capsule, and a small, angular-celled growth inside.

A report on the nature of the tumor was requested for the next meeting.

CORRESPONDENCE.

SUDDEN DEATH DURING OR SOON AFTER CONVALESCENCE FROM DIPHTHERIA.

To the Editor of THE MEDICAL NEWS.

SIR: I would be glad to add another case of sudden death during or soon after convalescence from diphtheria to those reported by Dr. J. Ferguson, of Toronto, Canada, in the issue of THE MEDICAL NEWS of December 15, 1883, page 649. The following case occurred in my practice in May, 1876.

F. B., a bright little boy of seven years of age, had, May 20, 1876, all the prodromal symptoms, which developed on the third day into an apparently mild type of scarlet fever. The fever was not high, the eruption comparatively light, and there was nothing manifested in the symptoms to indicate anything of a serious nature except the throat, which was intensely red and swollen, the tonsils and half arches so approximated as to shut out the view beyond, and here and there appeared specks of gray deposit of a suspicious character, and evidently portending danger.

The scarlatinal symptoms gradually subsided, but the throat symptoms increased in greater proportion. The entire throat, tonsils, fauces, soft palate, pharynx, and naso-pharynx, covered over rapidly with a thick, tenacious diphtheritic membrane, becoming quite offensive, and impeding respiration to such a degree as nearly to cause suffocation. It was only by the continued use of the probang, and an arrangement like a bottle-washer, a stiff spiral brush on a long wire handle—the brush being thrust in after opening the mouth and moved back and forth quickly as in cleansing the tube after operation for tracheotomy—that breathing could be kept up. The child soon became comatose, and continued in a drowsy condition most of the time, which aided the operation of cleansing the throat, and it was not until

the 6th of May, that any idea was entertained that he would survive, but to the surprise of all, he commenced to mend—the membrane began to disappear from the throat, allowing him to breathe through the mouth—that in the naso-pharynx remained longer, and obstructed nasal respiration for some time after.

As with most children during convalescence from protracted illness, he became very fretful and hard to manage, and further treatment, especially applications to the throat, was almost impossible, and had to be suspended for fear that, in his struggles, an accident might occur. He went on, however, seemingly well, until May the 11th; I visited him at 7 P.M. of that day as usual, and left him apparently doing well. In half an hour after I had seen him, I was apprised by a messenger that he sat up in bed to be fed, and while in the act suddenly fell back and expired.

I considered the remote cause of death in this case to be asthenia, and its immediate cause heart failure—failure to carry on its intrinsic work in the erect position. It is generally conceived that such cases terminate by death beginning at the heart, sometimes from paralysis, and sometimes by thrombus. I cannot say whether or not the emotional element had any immediate relation with the final termination in this case.

S. J. RADCLIFFE, M.D.
1211 F. STREET, N. W., WASHINGTON, D. C.

NEWS ITEMS.

AN INTERNATIONAL CONFERENCE.—In his annual report, Surgeon-General Wales recommends that the medical departments of the great naval powers be invited to a general conference, with a view to the adoption of a uniform nomenclature, classification, and tabulation of diseases, and of a system of interchange of periodical reports of the movement of disease, from which international reports of sanitary conditions all over the world may be published at stated intervals.

THE NEW SEWAGE SYSTEM OF BOSTON.—The great sewage system which has been in process of construction in Boston for several years is now completed, and last Tuesday its pumps were set in motion. This system, which constitutes one of the greatest engineering feats of the age, and is pronounced even superior to that of Paris, has for its object in brief, the interception of sewage as it flows in the existing sewers, and its conveyance to a point where it may be discharged with safety to the public health, and with the smallest possible injury to other interests.

For this purpose a large sewer has been built along the marginal streets of the city, intercepting all existing drainage by means of numerous branches, and finally terminating in a pumping station at Old Harbor Point. Here four engines, with a daily pumping capacity of 25,000,000 gallons, are erected together, with screens for the stopping of large objects. The outfall sewer, which extends thence to a reservoir on Moon Island, consists of three sections: first a tank, second a tunnel under Dorchester Bay, and third a large land sewer. At Moon Island, where the sewage is discharged into deep water, there is a large reservoir covering several acres. It has four compartments, and will hold nearly 25,000,000 gallons. Its design is such that it can be conveniently enlarged at any time to double this capacity to meet the needs of the increased growth of the city. A large number of gates are provided for admitting and discharging sewages, which are to be opened by hydraulic pressure, as are those at the pumping station.

The last link in the extensive chain of works is the outlet section, which contains four sewers, so arranged as to connect with the outfall sewer in receiving the discharge from the reservoirs and carrying it out to the tidal current at the end of Moon Island. The entire cost of this system has been $4,544,272.89.

ARCHIVES OF MEDICINE.—It is announced that the *Archives of Medicine* has discontinued publication after a satisfactory existence of five years. This suspension is rendered necessary not from lack of support by contributors or subscribers, but through a combination of extraneous circumstances.

NEW MEDICAL JOURNAL.—*The Archives of Pediatrics*, a monthly journal devoted to the diseases of infants and children, edited by DR. WILLIAM PERRY WATSON, of Jersey City, has recently issued its first number, containing sixty-four pages of reading matter. The collaborators number thirteen; of these, nine are selected from the principal medical centres of the United States, one from Canada, and three from England.

BANQUET TO CHARCOT.—The old pupils of M. Charcot tendered him a banquet on December 5, on the occasion of his nomination to the Institute. Congratulary telegrams were sent by those unable to attend.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending December 22, 1883, indicate that influenza, remittent fever, rheumatism, consumption, and bronchitis have increased, and that diarrhœa, pneumonia, measles, typhoid fever, inflammation of kidney, and scarlet fever, have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending December 22, and since, at eight places; scarlet fever at fourteen places; and measles at three places.

OBITUARY RECORD.—Died, in Washington, D. C., on Sunday December 30th, in the sixty-eighth year of his age, JOHNSON ELIOT, M.D.

From 1828 to 1839 Dr. Eliot was engaged in the drug business; in the latter year he began to study medicine under Dr. Thos. Sewall—being at the time Steward in the Naval Hospital. He matriculated at the College of Physicians and Surgeons of New York, and received his degree of Doctor in Medicine in 1842. Immediately upon his graduation he was appointed Demonstrator of Anatomy in the College, and in 1850 Professor of Anatomy in Georgetown University. In 1861 he accepted the Chair of Surgery in this institution, retaining it until 1876, when he was made Emeritus Professor of Surgery and Professor of Clinical Surgery. In 1869 he received from Georgetown University the honorary degree of A.M., and in 1872 that of Doctor of Pharmacy.

NOTES AND QUERIES.

A STATEMENT.

To the Editor of THE MEDICAL NEWS.

SIR: Will you kindly publish the following statement, made necessary because of my receiving letters from England and this country calling my attention to the liberty taken with my name.

Dr. H. H. Kane, of New York, has made use of my name in an advertisement of a secret means of treating the opium habit; and afterwards, in a pamphlet labelled "De Quincy Opium Home Cure," containing printed fac-similes of letters received by him years ago from a number of physicians, and among them a letter of mine. In obedience to a protest on my part, Dr. Kane has removed my name from his advertisement, and my letter from his pamphlet.

Yours truly,

S. WEIR MITCHELL, M.D.

December 22, 1883.

NERVOUS ACCIDENTS CAUSED BY THE MATERIALS OF PHOTOGRAPHY.

To the Editor of THE MEDICAL NEWS.

SIR: Permit me to direct your attention to the statement made in the article "Nervous Accidents Caused by the Materials of Photography," in your issue of December 15th, that the vapor of prussic acid is formed by "the decomposition of cyanide of potassium by bichromate of potassium."

It is well known that the vapor of prussic acid is given off by cyanide of potassium at ordinary temperatures even without the addition of an acid or acid salt. If these be added, the amount of vapor given off is, of course, increased; but in photographic operations, the two substances named are *never, under any circumstances, mixed together*, as might be inferred from the article.

Again, reference is made to the deoxygenation of the air of the operating room to an injurious extent by the affinity of the developing solution of pyrogallic acid mixed with an alkali (ammonia) for oxygen. This is absolutely impossible; the amounts used being so small that a lighted gas-burner (even if turned down low), or an assistant, would consume far more oxygen, and throw off perceptible quantities of carbonic acid. Sixteen grains of dry pyrogallic acid mixed with a drachm of strong ammonia would develop a plate much larger than the average of those used in photographic galleries, and although some oxygen is undoubtedly absorbed, it is not at all dangerous to health.

Thirdly, the mention of ether is made in connection with the gelatino-bromide process, so that it might reasonably be inferred by the non-photographic reader that the former played some part in the latter. This is plainly an oversight, the entire absence of any form of spirituous solvent being well known to all who are conversant with the said process.

Permit me to say, in conclusion, that I concur fully with the general idea expressed in the article as to the necessity of caution in the handling of dangerous chemicals, and the risk run by any one confining himself in the dimly lighted and close dark-room for too long a time.

Very respectfully yours,

ELLERSLIE WALLACE, JR., M.D.

1130 SPRUCE STREET, Dec. 20, 1883.

THE NATURE OF SYPHILIS.

To the Editor of THE MEDICAL NEWS.

SIR: In the review of the excellent work of Bumstead and Taylor on *Venereal Diseases*, fifth edition, in your issue of Dec. 22, 1883, the reviewer says, "In the chapter on the nature of syphilis, there is a somewhat indignant denial of the recently repeated claims of Dr. Otis, that Bumstead and Taylor have adopted his peculiar views as to the nature of the syphilitic virus, and the process of its absorption and distribution through the system."

This appears so much like a question of veracity between the surviving author and myself that I feel impelled to ask the privilege of a statement of my position in this matter in connection with this review. The "recently repeated claims" alluded to may be found in the preface of my book on *Genito-Urinary Diseases and Syphilis* (New York, 1883), page 7, as follows:

"The first authoritative publication which followed *practically* adopted and supported the new views, thus, 'The secretions of syphilitic lesions are found to consist of a serous fluid containing numerous granules or molecules, which are masses of protoplasm or germinal matter, holding the contagious properties of syphilis. *These microscopic bodies are probably taken into the circulation by the lymphatics and conveyed over the body.* . . . . In the secondary period of syphilis, these *cells* are very numerous, and the body may be covered with papules and tubercles *composed of them.* . . . As the disease wanes . . . the cells no longer have the tendency to reproduction which characterizes them in the early stages, but rather degenerate. *Hence we consider the blood and the secretions, in tertiary syphilis, innocuous.*'"

It is scarcely necessary for me to say that these views of the nature and behavior of syphilis, as embodied in the foregoing extract, are *identical* with those presented to the profession by me in 1868, and plainly set forth in my papers before the New York County Medical Society in 1870; also in my book on *Syphilis*, published in 1878, and later in my book on *Genito-Urinary Diseases and Syphilis*, published in 1883.

The denial referred to has not been accompanied by a withdrawal in the new edition (fifth) of the description of the nature of syphilis given at page 443 of the previous edition. It is true that these views are not distinctly credited to me, *as they should have been*, but occur in the body of the text as the views of the authors. In a note on the same page they even disclaim that my views are worthy of consideration.

The fact still remains that they are presented, as above stated, *as the views of Bumstead and Taylor*. Unless, therefore, it can be shown that the views above referred to are *not* those which I first published in 1870, and subsequently reiterated, it must be acknowledged that, by their publication in the work of Bumstead and Taylor, in form as previously stated, they in that way *practically* support my views, as I have claimed, however earnestly and persistently they may strive to ignore my connection with them.

Very truly yours,

F. N. OTIS, M.D.

THE "AMNIONTOME."

To the Editor of THE MEDICAL NEWS.

SIR: Under the head of "New Inventions," in your issue of December 8th, I find a description, and illustration by woodcut, of a new instrument, called by its inventor the "Amniontome." It is claimed by the inventor, also, that there has been a long-felt need in the armamentarium of the obstetrician of a contrivance whereby he could certainly and easily rupture the amniotic membranes when it was desirable to do so, and that now the vacuum had been filled. He states that the finger-nail sometimes fails, and that he has been obliged to resort to such awkward procedures as the introduction of knives and scissors to accomplish the desired end.

Truly, I should say that the introduction of knives and scissors for such purposes is a very awkward procedure, or, in fact, the introduction of any other sharp-pointed instrument for such purpose. Now, if I understand the nature of this "amniontome," it is a sharp-pointed instrument, arranged with a mechanism whereby it can be attached to either index-finger, while the puncturing or pointed portion extends beyond the finger's end a short distance. We are not informed of the length of the instrument; but this matters not. It is intended that this piece of insensible and pointed steel is to precede the sensitive and educated index-finger on its way into the vagina, and to the accomplishment of the desired end—the puncture of the amniotic membranes. I was taught, and have always practised, and believe it always should be practised—not to introduce *any* sharp instrument into the vagina unguided by the sense of sight or touch.

It is possible that this little "corn husker" may be introduced without puncturing any tissue not intended to be punctured; but the risk of so doing is always present before the operator. It violates the rule which I have just stated, and is, therefore, reprehensible. I should say that the introduction of a knife or a pair of scissors along the palmar surface of the already introduced index-finger is a far more rational procedure. In this case you know where your instrument is going, but in the other the instrument precedes the sensitive finger.

Let me state a more rational procedure than to use *any* sharp-pointed instrument; for such sharp instrument is not required to accomplish the end under discussion. Let us suppose that the obstetrician is sitting to the right of his patient, and, therefore, using his right index-finger for vaginal examinations, etc. Now introduce the right index until it comes in contact with the bulging and resistant membranes; then carry the ordinary grooved director of the pocket-case, held in the left hand, *over* the right thigh of patient, and introduce its blunt point along the palmar surface of the introduced finger until it also comes in contact with the sac of waters. When the next uterine contraction supervenes, by gentle pressure it readily penetrates the membranes, and the desired end is reached without the least particle of hazard to the mother's tissues Some other blunt instrument would answer as well as the director mentioned, but this is usually at hand. Sharp-pointed instruments are never required for this simple operation, and should not be used unless others are not at command, and then only when guided by the educated index.

Respectfully,

A. C. SIMONTON, M.D.

ORIGINAL LECTURES.

VAGINITIS AND VULVITIS.

A Clinical Lecture, delivered at the Long Island College Hospital.

BY ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF GYNECOLOGY AND SURGEON TO THE LONG ISLAND COLLEGE HOSPITAL.

(Reported by Edward Develin, M.D.)

GENTLEMEN: The first case to which I call your attention is one of vaginitis. This patient complains of a discharge from the genitals, and upon examination we find this discharge to be leucorrhœal in character. We also find a prolapsus of the anterior vaginal wall. The previous history of this case tells me that we have missed the opportunity of seeing its pathology when most marked. When she presented herself at the clinic a few weeks ago, she gave a history of acute vaginitis; she then had the profuse purulent discharge so characteristic of this disease. The fact that this was developed abruptly has its significance; bear that in mind, because in diagnosticating the cause of vaginitis we often have much difficulty. It is not easy to differentiate between an ordinary vaginitis which is caused by uterine disease, and the specific vaginitis which is of gonorrhœal origin. The most important point in the history that I know of, is in the difference of the onset of the attack. In the benign or non-specific variety, it comes on slowly, the patient usually having the history of some preëxisting uterine disease, and then by degrees the vaginitis is developed, slight at first, and gradually growing worse; whereas the specific vaginitis is developed promptly, and is more likely to begin at the introitus and extend upward—that which is consequent on uterine disease descends downward, and rarely involves the urethra and meatus. These points are important, and we should always bear them in mind, as it is impossible to differentiate by the mere physical signs. I have seen, especially among insane people, a vaginitis which I knew was not gonorrhœal, as there was no means by which the disease could be contracted, and yet it was extremely difficult to be sure that it was non-specific, and due only to some uterine disease or to the filthy habits of the patient herself. In these large asylums, it being almost impossible to keep the patients clean, so that a vaginitis once started is likely to become severe, I have seen vaginitis so marked that I could not distinguish its character by the physical appearances, and I was enabled to make the diagnosis only because I knew the patient could not have been exposed to the specific cause.

When a vaginitis begins abruptly; when it involves introitus, meatus, and urethra; and when you find that it does not extend the entire length of the vagina, you may take it for granted that it is specific—this is a strong evidence in its favor. Or if you have the good fortune, as I did the other day, *i. e.*, a gentlemen, whose wife was under my care, came to me and said, "Doctor, I am afraid you may find new developments in my wife's case, as I have exposed myself;" now when you have a history of that kind and which develops under your observation, then you know what it is.

In reference to our patient here it is a case of specific vaginitis, and Dr. Cushing, under whose care she has been, has almost relieved her of this difficulty.

As regards the treatment of this disease, it is simple and always satisfactory, if you adopt the best possible means of management. The great object is to keep the parts clean; the longer this purulent formation is allowed to remain in contact with the tissues the more it irritates and aggravates the disease. We could cure a vaginitis in a few days if we could keep the vagina perfectly clean.

In some neglected cases I adopt this plan, viz., separate the inflamed vaginal walls, and keep them apart by marine lint, so that the moment the purulent discharge is thrown out it is absorbed; it is simply a method of treatment according to the rules of antiseptic surgery, disinfecting the parts as the discharge forms. The douche, however, is very effectual. It prevents the accumulation of the discharge; if you allow the patient to lie on her back with the hips elevated, and then use the fountain syringe for half an hour four or five times a day, you will succeed in your treatment very well. It is not so much the preparation which you use, as the thoroughness of its application, and the care and frequency with which you use it; keep the surfaces of the mucous membranes perfectly clean, that is the great object.

I saw the other day, in one of the English journals, a mode of treating gonorrhœa in the male by just this method; using the return-current urethral douche, and then introducing a medicated bougie to keep the surfaces apart. The record of the length of time required to effect a cure in these cases was from three to ten days; and those who have had the treatment of such cases know that this record is most extraordinary. I saw at once that the surgeon secured his good results from this method of perfect cleanliness, and it confirmed my experience that this vaginitis can be cured in the same way.

Another point in the disease is that it is very liable to remain latent in some fold of the mucous membrane; generally behind the cervix the disease will lodge and linger. I learned a very important lesson when I first commenced the practice of gynecology. I had a case of vaginitis which I cured repeatedly, but she did not remain cured, and finally I sent her to the late Dr. J. Marion Sims; he wrote me a very kind letter, and told me that I had overlooked a little pocket where the disease lingered, and that from this point the disease again started. He told me to expose the parts with his speculum, and I would find this little pocket behind the cervix in the fold of the mucous membrane, and which I had failed to cleanse with my douche. I then carefully examined the patient, and found it as he described; then

carefully cleansing the parts I had no difficulty in effecting a permanent cure.

This trouble, when it involves the urethra, is liable to creep up into the two urethral glands which lie just within the meatus, and remain there; so that you may cure the vaginitis, and it will then start afresh from this source. After I had called attention to the anatomy and pathology of these glands, as secreting the gonorrhœal discharge, a physician in Illinois published two cases, those of husband and wife, which he had cured repeatedly of gonorrhœa, but the disease constantly returned. He then discovered the gonorrhœal inflammation of these glands; apparently to all external appearances the parts were looking well, but by pressure upon the urethra of the woman he could cause a little drop of matter to escape. He then laid the ducts open and was enabled to cure the disease.

If you will remember these two points, you will have no difficulty in treating vaginitis, and your patient will not return in a few days and inform you that your treatment has not effected a permanent cure.

Case II.—My next patient is a little girl, whom I understand is suffering from vulvitis or vaginitis. I have already presented such cases to you, and told you that this occurs in those children suffering from struma or ascarides, and sometimes in those who are tolerably healthy, who, running around until they become excessively warm, sit down upon a cold stone and take cold, getting up a little catarrhal inflammation of the vulva. Now here we have the physical signs in quite a marked degree of the ordinary catarrhal or purulent vulvitis which occurs in children. The outer parts of the vulva are covered with dried pus, while further in are little masses of muco-purulent material. This is just such a case as you will often meet with, and I desire you specially to notice the character of this discharge. This vulvitis is exceedingly annoying, and not uncommon, by any means; it is also very difficult to cure, unless you have great patience. They are extremely difficult to cure in case they are complicated with vaginitis. Now I presume, from my present examination, that there is only vulvitis; I will tell you why: because she has the characteristic discharge of vulvitis alone, that is, a muco-purulent discharge, somewhat tenacious—you observe how it hangs together. When vaginitis is present with the vulvitis, we get a milky discharge, very abundant. I have seen a little girl of this size who would saturate her garments with the discharge so that when they were dried they would be as stiff as if they had been starched. From the absence of this profuse milky discharge I am inclined to think that we have vulvitis alone, and no vaginitis. In vaginitis, even though the vaginal discharge be purulent, it remains fluid, not tenacious like that which comes from the vulva. You will usually be able to make your diagnosis by the character of the discharge.

This child is also suffering from otorrhea; and, more than that, she has a sister who suffers from this vulvitis; so I have no doubt in my mind, from the fact that both of them have it, that it is due to a scrofulous diathesis; for, as you are all aware, in that peculiar constitutional condition we are prone to have inflammations of the mucous membranes. They are the little ones who get up this inflammation of the eyes, this blennorrhœa at birth, and, if they escape that, they may have the condition which you see in this child.

In reference to the management of cases of blennorrhœa, the oculist will tell you that it is a matter of care and cleanliness. It is precisely the same in vulvitis and vaginitis; if you will only keep the parts clean, they will get well. This, however, is no easy matter when treating the poorer classes. The longer you permit this discharge to remain, so much the more will this inflammation be kept up. This little one should be bathed constantly, every two or three hours during the day; carefully wash the parts with a little borax and water, and then apply some dry powder; the one that I prefer is bismuth mixed with a little chalk, have it finely powdered and dust it on; iodoform also answers the same purpose, but the odor is not very pleasant. These applications have a soothing and quieting effect upon the mucous membranes, and keep the surfaces apart. This is a very important item in treatment, because two inflamed parts lying in apposition cause an internal irritation.

In vulvitis this is about all you will have to do locally. You must keep up persistent cleanliness, and also attend to the general health of your patients; build them up with good diet, cod-liver oil, iron, and so forth. If you do that, they will get well. But it is otherwise if you have vaginitis; you then have to use a vaginal douche, carrying it up carefully to the end of the vagina, and carefully wash the part with a solution of borax and water; afterwards washing it with a mild solution of zinc or hydrastis canadensis. These cases are extremely difficult to cure, because the mucous membrane of the vagina is full of deep rugosities, and the wash does not come in contact with all parts. You therefore require to distend the vagina as much as possible while using the local applications, but even then there may be little places where some of the discharge will remain, and by and by it will beget the old trouble anew. Some authors say that if you have tried all these means and failed, it is better to place the patient under an anæsthetic and then, distending the vagina, touch every part of the mucous membrane with a solution of nitrate of silver, and follow it up with a douche.

This is about the outline of the treatment required; eternal vigilance is the price you have to pay for success. Still more, you must superintend the treatment yourself, unless you have a very intelligent mother or nurse to carry out your instructions.

ORIGINAL ARTICLES.

THE EXPERT TESTIMONY IN THE DWIGHT INSURANCE CASE.

BY HORATIO C. WOOD, M.D., LL.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF DISEASES OF THE NERVOUS SYSTEM, IN THE UNIVERSITY OF PENNSYLVANIA.

THE so-called Dwight case bids fair to become not only a landmark in the history of insurance law, but also a *cause célèbre* in the annals of medico-legal medicine. As one who had taken part in it, I had intended to say nothing about it; but some misconceptions as to the facts and certain reflections upon a body of physicians of more or less eminence, which have gained currency, have led

me to believe that the facts of the case ought to be known to the whole profession.

As the evidence elicited at the trial has not as yet been published, it can only be known to those who have heard it in its entirety or have access to one of the three extant copies of the stenographic notes. *Inside* the court-room the experts have been remarkably free from serious disagreement, because they were confined to the testimony; but *outside* the court-room the criticising expert has roamed at will through the realms of imagination and *ex-parte* testimony. *Inside* the court-room there was no evidence to show that overdoses of morphia were given, and no medical man there ventured to assert that Col. Dwight died from other cause than strangulation.

All medico-legal discussions of an individual case, if they are to lead to any proper result, must be based upon the facts sworn to at the trial; *i. e.*, upon the evidence on which an opinion had to be given at the time of the trial. Especially is this limitation necessary when experts are arraigned at the bar of public opinion.

The action of the experts in the present case has been open and honorable; but, as it has been publicly challenged, I propose to give, primarily, such history of it as will not appear in the account of the evidence.

About the first of June, 1883, I received a telegram from Prof. Austin Flint, Jr., requesting that Drs. Roberts Bartholow, Theodore G. Wormley, Isaac Ott, and I, should meet him the next day at my office. At the interview we were informed by Prof. Flint that he desired to see us concerning the Dwight case, as the lawyers and the Insurance Committee, believing that Col. Dwight had died of gelsemium poisoning, had requested him to procure a professional opinion from us upon evidence furnished in a privately printed book, copies of which he put in our hands. We were expressly told that these books were to be considered as confidential communications; that the matter contained in them was not legal evidence which had been sifted and could be relied on, but that it was a collected mass sufficient to indicate the probable drift of the evidence at the trial.

Dr. Flint remained only a few minutes, and did not in any way attempt to influence our decision. We separated, met by appointment twelve hours later, and found that we had separately reached the same conclusion, viz., that the death of Col. Dwight was probably caused by strangulation. Prof. Bartholow was most positive and outspoken in this opinion; Dr. Ott the least certain and positive; Dr. Wormley, whilst acquiescing in the opinion as a matter of belief, said that it was too much out of his line for him to give evidence. This conjoint opinion was given to the Insurance Companies with the reserved statement that we had no evidence that the heart had been properly examined, and that, therefore, there was that element of doubt. It was subsequently proved at the trial that microscopical examination of the heart had been made, although the report had not been furnished us.

In regard to the relations of the other experts. Prof. C. H. Porter, of the Albany Medical College, was originally employed by the Insurance Companies to visit Mr. Dwight in his lifetime. At the time of the first autopsy he was hastily summoned by telegraph to attend, and being unable to go, on the instant, selected Dr. John Swinburne as the best substitute he could procure. Dr. Swinburne's connection with the case was, therefore, accidental. He was not asked to go by the Insurance Companies, or their legal representatives, but by Dr. Porter, as a personal favor to himself. The testimony of Dr. Swinburne in the trial was not only in matters of opinion, but also in matters of fact. If the facts sworn to by Dr. Swinburne are as he alleges, I can but reiterate my opinion expressed upon the stand, that there is no room for doubt as to the cause of death.

As bearing upon this I may be allowed to quote the following passage from Taylor's *Principles and Practice of Medical Jurisprudence:*

> "The act of strangulation should be, medically speaking, as distinctly provable, without the production of a rope, as the act of stabbing without the production of a knife which inflicted the stab. If these principles are not adhered to in practice, policemen would be as competent as medical experts to give evidence of the causes of death in cases of alleged strangulation." (P. 65.)

Under these circumstances, it is proper to state that Dr. Swinburne has had a long, successful professional career, in which he has enjoyed very large opportunities for making observations upon all sorts of causes of death, and has been at various times engaged in medico-legal work. It seems to me absurd to question his ability to distinguish a rope-mark from a wrinkle. The lesions of the body were not such as to require great skill in their perception. They were simple and gross in character. It must also be remembered that, in almost all points, Dr. Swinburne's testimony has been corroborated by the notes of the autopsy, signed by fifteen physicians without comment; as well as by the appearances at the second autopsy. Drs. B. F. Sherman and E. H. Bridges, who attended the second autopsy, are men of high reputation in northern and western New York, and have had large experience in medico-legal practice.

The following history of the case is based exclusively upon the evidence given at the trial, and is believed to contain all the facts, of any importance to the medico-legal questions, which were proved at Norwich. The corrected evidence, which will be published as soon as possible, will certainly be accessible, so that any one may verify in all its details the story of which I am about to give the outline. In this history, I might, perhaps, have confined the attention exclusively to the medico-legal facts, but it has seemed to me that the reader would prefer to have the whole story in brief, as it is one of great psychological as well as of medico-legal interest.

Col. Dwight, after the War of the Rebellion, was occupied in business in northern Pennsylvania, and moved in 1872 to the city of Binghamton, New York, where he engaged in very large building speculations. During much of his life in Binghamton he was proprietor and manager of the Dwight

House. As he described himself, he was a man accustomed to "bore with a big auger." His business operations had always been on a grand scale, and largely based upon borrowed money. According to his own sworn statement, he had lived at the rate of eighteen thousand dollars a year, and had accumulated four hundred thousand dollars of debt, besides dissipating his wife's fortune, and rendering her insolvent to a large, if not almost an equal, amount. He finally was beset on all sides by creditors, members of his wife's family being among the most rapacious and exacting. In testimony given in 1878, during the bankruptcy proceedings which he had instituted for his relief, he swore as follows: "I received a notice that Dusenberry [who was his wife's uncle] was about to sell the equity interest in this estate, thereby sweeping the last plank from under me." Again, he says, "It was just like killing me, and I felt as though I was sold out by everybody and everything." At another time, in the same proceedings, he stated, under oath, that he had but eight dollars "on the face of the earth," and his wife but two dollars; and that he was borrowing money from his brother Ward to pay the bills for board of himself and wife at the Spaulding House.

Col. Dwight was not discharged from bankruptcy until November 6th, nine days before his death; but on the 31st day of July he began to apply for life insurance, and before the middle of September had made formal applications to thirty-one companies for a sum in the aggregate of three hundred and ninety thousand dollars, requiring annual premiums of about thirteen thousand dollars. Taking his application in the case immediately on trial, that of the Germania Life Insurance Company, as a type, Col. Dwight answered in it the following questions as follows:

1. In what occupation has he been engaged during the last ten years. *Ans.* Real estate and grain dealer.
2. Is he now, or has he been, engaged in or connected with the manufacture or sale of any beer, wine, or other intoxicating liquor? *Ans.* No.
3. Whether the party to be assured is now, or has been, insured in other companies; in which, and for what amount in each? *State exactly on what kind of policy. Ans.* Yes; New York Mutual, fifteen year endowment, ten thousand dollars; Connecticut Mutual, ordinary life, fifteen thousand dollars; Washington, ordinary life, ten thousand dollars; Equitable, ordinary life, ten thousand dollars.
4. Whether an assurance has been applied for with this or any other company without having led to an assurance; if so, with which companies; and for what reason did the application not lead to an assurance? *Ans.* No.
5. Has the party now, or has the same ever had, any of the following diseases: Spitting of blood, bronchitis, consumption, etc. *Ans.* No.

1. It was in evidence that Col. Dwight, during his bankruptcy proceedings in 1878, swore that his whole occupation from 1872 consisted in fighting his lawsuits and keeping the Dwight House.

2. It was proved, and not disputed, that he sold liquors during the whole period of time which he kept the Dwight House.

3. It was proved, and not disputed, that he never was insured in the New York Mutual Life, nor in the Connecticut Mutual Life.

4. It was proved, and not disputed, that he had made applications to the Phœnix Mutual Life Insurance Company and others, which had not led, and never did lead, to an assurance.

5. It was proved by several witnesses that he had, in March 1867, severe cough with repeated spitting of blood, amounting in at least one instance to a copious hemorrhage, and that he had repeatedly said that he had had hemorrhages from the lungs; also that he "expected the damned thing would carry him off." This testimony was not disputed by the plaintiff, who admitted the spitting of blood, but claimed that it was not a disease. At the apex of one lung, at the first autopsy, was found a "cicatrix," or "fibrous nodule," a lesion which was noted on the official notes subscribed to by the fifteen physicians present as being "probably the result of old pulmonary phthisis."

Col. Dwight warranted that his answers to the above questions were true, and the contract provided that if any of the answers in the application were in any respect untrue the policy should be null and void; so it is perhaps allowable to state that it is upon these questions and their false answers that the counsel of the Insurance Companies have always, and still do expect to win their case. They assert that the law in New York State requires the judge to decide upon the legal points, and not to allow a case to go to the jury when there is no conflict of testimony. They have always recognized the extreme difficulty in getting a jury to decide a life insurance case upon its merits. The medico-legal investigation was entered upon by the Insurance Companies against the advice of their counsel, who proposed, as above stated, to contest the case purely upon the ground of false answers; but the companies were not willing to win the case upon purely technical grounds. They urged that they were refusing payment because they believed that fraud had been perpetrated, and that there had been conspiracy to rob the funds which had been entrusted to their care; and that they wished the public to understand that their strenuous resistance was based upon moral grounds, and upon the belief that if this raid were successful others would follow.

The counsel for the defence were adverse to the theory of suicide by strangulation even after receiving the opinions of Drs. Swinburne, Sherman, Bridges, and others, and therefore sent copies of the autopsy to experts in New York and Philadelphia, in the hope of obtaining opinions that the death was caused by vegetable poisons, which Col. Dwight could have taken without the knowledge of any other person. When the opinion of the Philadelphia council of experts was given, they expressed great chagrin, stating that if Col. Dwight was murdered the policies would have to be paid, whilst the theory of assisted suicide involved the indirect trial of at least Mr. Charles A. Hull as an accomplice. They not only were very adverse to the theory as a troublesome one, but did

not believe it to be true; and I will not soon forget my own astonishment when, during the latter part of the trial, one of them said to me "You experts have finally convinced me that Col. Dwight was strangled."

To return from this digression to the story of the last months of Col. Dwight's life. By the 22d of September, 1878, he had been either accepted or rejected by every life insurance company in the country, excepting one in California, and had secured in all, policies of insurance representing two hundred and fifty-six thousand dollars, and requiring for their maintenance an aggregate annual payment of over eight thousand dollars. He was at this time in bankruptcy, living at his father-in-law's house, without profession or business, or any apparent source of income. There was no evidence to show that Col. Dwight had at this time any scheme or plan for large enterprise upon hand, unless it was, as claimed by the defence, that of defrauding the Insurance Companies. Whenever it was possible, Col. Dwight stipulated that the premiums should be paid quarterly, and, when the rules of the companies did not allow this, semi-annually. In this way the annual expense was increased about one thousand dollars, but the first payment was reduced to a minimum. The first quarter's premiums were all that were ever paid, and these were paid with borrowed money, the lenders becoming beneficiaries under the will, which was executed in September, 1878. Before all of the coveted policies were secured, several of the insurance companies discovered the falsifications in the applications, and became convinced of the fraudulent character of the transaction. The delivery of some policies already in the hands of the agents was stopped by telegraph; in other cases Col. Dwight persuaded the agent to send word to the company that the policies were already delivered and the premiums paid, when no delivery or payment had been made.

Whilst Col. Dwight was still in perfect health various companies sent to him accredited agents with the statement that as the policies had been obtained by fraud no more premiums would be received, and that in case of his death no insurance would be paid to his heirs, and offered to him in money the amount of premium already paid, at the same time demanding back the policies. The proffered return-premiums and the demanded surrender of the policies were alike refused. During the month of September and the first ten days of October, Col. Dwight spent most of his time in hunting in the neighborhood of Windsor, N. Y., over a country which is extremely hilly or semi-mountainous. About October 11th it was announced that he was unwell. News of his alleged illness reaching the insurance companies, their suspicions were aroused, and Dr. Charles H. Porter was sent to see him on November 6th.

To put in this article the details of the evidence given by the physicians who saw Col. Dwight during life, or after his death, would occupy more space than can be claimed. The statements of the medical gentlemen are embodied in the hypothetical questions, concerning the agreement of which with the evidence there was at the trial no dispute whatever, and it is believed that the physician reading this article can decide for himself and answer as though an expert at the trial. Suffice it then for the present to state that Dr. Porter found, after very careful examination, nothing abnormal with any of the organs of Col. Dwight, and obtained from Dwight's physician, in his presence, the history of an obscure illness in which the only objective symptoms had been some vomiting and some evidences of a paroxysm said to resemble an attack of pernicious fever, but which had lasted only a few minutes, and in which the temperature had not risen above or fallen below 98½°, and the pulse not above 80. Suspecting that Col. Dwight might be suffering from chronic arsenical poisoning, Dr. Porter asked for a specimen of his urine for chemical analysis, but was met with the reply that Fowler's solution was being administered, and that therefore arsenic would of necessity be in the urine.

The evidence for the defence gave no account of what transpired in the history of Col. Dwight between the 6th and 15th of November.

In order to obtain some information concerning the day of his death, Mrs. Owens, the sister of Mrs. Dwight, was placed upon the stand. According to her statement, the apartments occupied by Col. Dwight were in a semi-detached cottage, which formed a part of the Spaulding House, in Binghamton. They consisted of a sitting-room, entered directly from a corridor, and communicating with a bedroom which was furnished with one window opening upon the ground. In the sitting-room was an open fire or stove. The bed in the chamber had a high head-board of such a character that it would be easily possible for a man to hang himself whilst in bed.

During the day of November 15th, Col. Dwight was up, dressed, saw various persons in his sitting-room, executed legal papers in a clear, bold hand, was bathed, and had his beard cut by the barber. Between 8 and 9 o'clock P. M., Mr. Charles A. Hull came. About half-past nine Dr. Dan. S. Burr came in, chatted a few moments and then left. Mrs. Dwight and Mrs. Owens left the room a few minutes after the Doctor, Col. Dwight bidding them good-night. They retired to their room on the other side of the corridor, where they slept together. At about half past eleven, they were aroused by a rap upon the door. Mrs. Dwight instantly arose and went to her husband's room, Mrs. Owens following in two or three minutes. Mrs. Owens found in the room Mr. Hull, W. F. Spaulding (the proprietor of the hotel), and Mrs. Dwight. Mr. Dwight gave no sign of life after she entered. He was supported on pillows, and Mr. Spaulding was trying to give him brandy, but desisted in a few minutes, saying that he did not swallow it. At the suggestion of some one, hot water was obtained and Col. Dwight's hands put into it. Something over half an hour after Mrs. Owens went to the room the undertaker arrived. Mrs. Dwight and Mrs. Owens then went into another room and went to bed.

In order to complete the story at this point, it is necessary to draw on the evidence furnished by

Neri Pine, the attorney of Col. Dwight, who was put upon the stand by the plaintiff. He stated that on November 15th he called on Col. Dwight to transact certain legal business, and to inquire concerning the funds for the payment of the second quarter's premium which would be due on the 19th. Col. Dwight replied that he had no money to pay it, but that he (Mr. Pine) had better see Mr. Dusenberry, his father-in-law, whom he (Col. Dwight) thought would advance the necessary funds. Mr. Neri Pine further stated that Col. Dwight gave him no reason for supposing that any arrangement had been perfected with Mr. Dusenberry, but told him "that he was going to make arrangements with his father-in-law."

By the morning after this interview, death had rendered unnecessary any call by Mr. Neri Pine upon Mr. Dusenberry's good-nature.

The last will and testament of Col. Dwight is a remarkable instrument, which ought to be read in its entirety to be thoroughly appreciated, but of which we can only afford space for a very brief abstract. In it he states that his only assets are the moneys to be derived from the life insurance companies, and that he does not consider himself morally or otherwise required to pay anything to his creditors, from whom he escaped through his bankruptcy proceedings, but directs a number of small sums, from $1.60 upwards, to be paid to certain small creditors, who are specifically named.

He then bequeaths large sums of money to the Judge of the Supreme Court of his district, and to several of the most prominent lawyers of Binghamton, including the District Attorney. He leaves the sums of $10,000, $5000, and $1000, respectively, for the purpose of giving annual banquets to the poor of the town, the Fire Department, and the Press of the town; and to the Binghamton Library Association he bequeaths $7500. He makes a bequest to each of the four churches in Windsor, a village near Binghamton.

After a number of small private legacies, the bulk of the money to be derived from the Insurance Companies is directed to pass to his wife and son; but if the wife shall not have been released from bankruptcy, her share is to go to the son, in order to prevent its being used for the payment of debts.

It was testified to upon the stand that in the last weeks of his life, Col. Dwight had said that "he would rather be in hell than be poor:" that he was very poor and expected to die soon, is strongly indicated by the specific directions in his will to pay certain very small personal debts With a comfortable income, and no near prospect of death, a man would hardly provide in his will for payment of his last week's milk bill, or shoemaker's account. His frame of mind is further evinced by his statement in the will: "I have lived to that age, and been subject to such experience, that I have no further ambition for myself beyond leaving my family comfortable, and with sufficient means to enable them to live as they were in the habit of heretofore, and also in making such friendly bequests to those who are endeared to me from association and kindly acts, as will leave pleasant memories behind me when I start on the long journey."

Fifty-eight hours after death the first autopsy was made on the alleged body of Col. Dwight. The results obtained were testified to on the part of the defence by Dr. John Swinburne, and are embodied in the first hypothetical question herein presented. A second autopsy was made about five months after death in the presence of various physicians. The results obtained were testified to by Drs. Swinburne, Sherman, and Bridges, and are also embodied, so far as they are of any importance, in the hypothetical question.

Before taking up these questions it seems proper to give a little more in detail the evidence submitted by the defence in regard to two or three points.

As to the *condition of the heart.* Dr. Swinburne testified that the heart was perfectly healthy in every particular, except that some little thickening was noticed around the edges of the valves, and that at the second autopsy he carefully examined the coronary artery and found it entirely normal.

Dr. Sherman testified that, at the second autopsy, he found the heart remarkably firm, and in a good state of preservation; that he had prepared about one hundred and fifty slides of its walls for microscopical examination, and found in each the muscular fibre perfectly normal. He had with him in court a number of these specimens, and offered them for examination by any experts who might be called by the plaintiff, but no such examination was made.

Dr. Austin Flint, Jr., stated that he had examined a number of these slides, and found the heart-tissues normal. Dr. H. C. Wood confirmed this condition of the muscle-fibre in the slides which he had examined. Dr. E. H. Bridges testified that he had examined the heart both macroscopically and microscopically, and found it normal.[1]

When it is borne in mind that Mr. Dwight was an athletic man, in the prime of life, forty-one years of age; had spent the last months of his life hunting in a hilly country without suffering from shortness of breath or other distress; that the lesions in the body were entirely diverse from those found after death from heart-failure; that the heart had emptied itself of blood, and ceased its action in systole; that there was no evidence whatsoever at the trial in any way contradicting the statements made by Drs. Swinburne, Sherman, and Bridges; that the heart, carefully examined macroscopically, appeared to be perfectly normal; and the assertions of Drs. Sherman, Bridges, A. Flint, Jr., and H. C. Wood, that the fibres were shown by microscopical examination to have their striæ well marked, and to be entirely free from degeneration—it seems to me that the question as to the condition of the heart must be considered as settled. Certainly no

[1] The perfect condition of the heart at the second autopsy was largely due to the fact that, after the closure of the body at the first autopsy, the undertaker poured into the thoracic cavity a pint of concentrated solution of carbolic acid, arsenic, camphor, and corrosive sublimate.

opinion that death resulted from heart-failure could be given upon the evidence furnished at the trial.

In regard to the existence of *superficial emphysema of the lung* as present at the first autopsy, Dr. Swinburne testified minutely and positively, although from some oversight this testimony was not embodied in the hypothetical question as to the cause of death as given a little later. Such recent, fresh rupture of the upper air-vesicles is, in itself, almost sufficient to prove that a man has died from an obstruction to respiration in the throat. To rupture the air-vesicles there must be great internal pressure, as of forced respiration, and prevention of the escape of the air, which then tears open those vesicles whose walls are not closely supported by other vesicles, or by tightly contracting muscles.

In regard to the alleged *furrow in the neck*, Dr. Swinburne testified that it

"Was a heavy indentation in the neck, commencing on the right side near the hyoid bone, and extending upwards and backwards to within, perhaps, an inch or so, and perhaps less, of the centre of the posterior part of the neck; on the left side, the same indentation commenced about the upper part of the cricoid cartilage, extended about the same angle upwards and backwards until the indentations came within an inch and a half of meeting. These indentations were full three-eighths of an inch deep, so you could lay your finger right in them, and about that in width—I should say full that. At the bottom of the indentation, there was a peculiar appearance, sort of leathery appearance, or had a half-burnt or scorched appearance."

Dr. Swinburne further stated that at the second autopsy this indentation was "plainly perceptible," "and the same peculiar condition which appeared before at the bottom of the indentation was present —that sort of leathery or hardened feeling."

Dr. Sherman testified that, at the second autopsy, he called attention to the deep furrow in the neck, and put his finger in it. He stated that "the texture of the skin within this furrow had a leathery feeling. It had what Casper calls mummified." That he had seen other cases where death had been caused by strangulation with a cord, and that the furrow had the same characters as in the other cases.

Dr. Bridges testified that "the furrow was rounded at the bottom, about one-eighth to about a quarter of an inch thick, I should judge, and a quarter to half an inch broad. The lower or bottom part of the furrow or groove was rounded, so that it fitted the convex surface of my little finger, that I passed through on each side. The base of the groove was hard, and had this appearance that has been described—a parchment look."

Mr. Nat. B. Freeman testified that he had, during the war, been accustomed to handling corpses, and familiarizing himself with their external appearances; that at the second autopsy he examined the furrow, found that it "was deep enough for my finger to go partially into it;" that the skin at the bottom of the furrow appeared hard; "the feeling was a hard feeling; its appearance was similar in appearance to old leather."

In regard to the *cause of death*, Dr. Swinburne gave as his firmly settled opinion, based upon personal knowledge of the external and internal appearance of the body, that the death had been caused by strangulation with a rope or cord.

The position of the other experts was judicial, so far as concerned the cause of death; they gave their opinions upon hypothetical questions which embodied the evidence as to facts which had been given and bore upon the subject.

There were several hypothetical questions given, but for want of space only the one which bore directly upon the main issue as to the cause of death is here inserted.

"You examine about fifty-eight hours after death, in the middle of November, the body of a man found dead at about 11 P.M., having been last seen alive one hour and a half before, and then apparently not in a condition of apprehension of sudden death; you find it to be the body of an unusually large and powerful man, great muscular vigor, with a considerable development of firm fat, forty-one years of age; you find nothing unusual in the appearance of the face and the general surface of the skin, except the presence of small dark spots indicating a little effusion of blood in the skin of the back and the back of the right arm; a furrow about the sides of the neck nearly meeting in front and behind, about the size of the little finger, rounded at the bottom, and the skin involved in the furrow dense and hard, and a surface like parchment; the furrow beginning in front just above the larynx and extending upwards and backwards at an angle of nearly forty-five degrees; the brain and membranes perfectly natural and healthy, except a clot of blood on the surface on one side near the top of the head, the clot being evidently of very recent origin, but not sufficient in itself to produce death; the lungs deeply congested with dark liquid blood, but presenting no evidence of inflammation, a few small fibrous nodules, and the bronchial tubes and windpipe deeply congested and filled with bloody mucus; the heart and the bloodvessels, including the valves of the heart and the vessels supplying the blood to the substance of the heart, absolutely healthy and natural in size and in every other regard, excepting a slight unimportant thickening of some of the valves; the cavities of the heart containing a very small quantity of dark blood; the liver, spleen, and kidneys absolutely natural and healthy, except that they, especially the kidneys, are deeply congested with blood and of natural size and weight; a small quantity of undigested food in his stomach, the mucous membrane of the stomach and intestines congested, and a small area of apparent inflammation about the size of a dollar in the stomach; finding all of the organs in the conditions stated, and the furrow made as described above, what, in your opinion, was the immediate cause of death?"

To this, Dr. Wood answered, the death could only have been produced by strangulation with a cord. After the cross-examination of Dr. Wood, experts were called, one after the other, until the Court refused to hear any more. In this way, Drs. Porter, Sherman, Bridges, Avery, Lee, and Hand (the latter three gentlemen being practising physicians and coroners or ex-coroners of Chenango County, New York) were allowed to answer the hypothetical question, and all agreed with the answer given by Dr. Wood.

The only evidence offered by the plaintiff bearing upon the medico-legal facts in the case was:

First. *In regard to the two alleged chills* occurring

during his illness—the last one a week previous to his death.

The only evidence given concerning these attacks was that of Mrs. Bessie McDonald and Mr. Francis Downe. It was so indefinite, and would require so much space for its recital here, that the reader is referred to the book of corrected evidence. From it it is impossible to state with any degree of positiveness what the nature of the attacks were. It is not probable that they were malarial, for in the first attack there was no fever, and in the second attack the fever lasted for "perhaps half an hour," and the chief symptom was abdominal pain.

The counsel for the plaintiffs offered to prove the symptoms and nature of the sickness of Col. Dwight, and the cause of his death, by Drs. Orton and Burr, who attended Col. Dwight in his last illness, and were each of them on the witness-stand. According to the law of the State of New York no physician is allowed to testify concerning a patient, or to give information which has been imparted to him by a patient, unless the latter publicly gives his consent. And when the defence in an early stage of the trial sought to put Dr. Doane on the stand to prove that Col. Dwight's hemorrhage came from the lungs, they were debarred under this statute. The counsel for the plaintiffs contended that the right of waiver passes to the executors of a dead man; but on the part of the defendant such interpretation of the law was strenuously resisted. Many hours were spent in legal argument, but the court finally decided in favor of the plaintiffs, and permitted Doctors Orton and Burr to testify as to their knowledge of the sickness of Col. Dwight, and the causes of his death. When, however, this right was granted, the counsel for the plaintiffs did not exercise it, and neither Dr. Orton or Dr. Burr was asked a single question concerning the symptoms of Col. Dwight's alleged last illness, or the causes of his death.[1] Under these circumstances it seems impossible for a professional man to attach importance to the statements made by persons without medical knowledge concerning the symptoms of the alleged illness. There are no important data other than that furnished in the evidence for the defence by Dr. Porter, even for deciding whether the sickness was real or feigned. There is certainly no proof that the alleged chills were not produced by overdoses of a depressing vegetable poison, and the gastric symptoms by overdoses of arsenic, both of which drugs were in Col. Dwight's possession and under his personal control.

Second. *In regard to the occurrences of the night of Col. Dwight's death.*

The only important testimony was that of Mr. Charles A. Hull. According to Mrs. Owens, Mr. W. F. Spaulding and Mrs. Dwight were already in the room of Col. Dwight when she (Mrs. Owens) entered directly after his death. It is altogether probable that Mr. W. F. Spaulding has intimate acquaintance with the circumstances surrounding the death of Col. Dwight. The defence could not call him since, according to their theory of the case, he had guilty knowledge, and if he should testify falsely, they, not being able to cross-examine or contradict their own witness, would be held by his declarations. The failure of the plaintiffs to put either Mr. Spaulding or Mrs. Dwight on the stand, naturally excited comment.

Mr. Charles A. Hull testified that he had never sat up with Col. Dwight until the night of his death; that he had been his assignee in bankruptcy, but not intimately acquainted with him; that he had no knowledge or experience in nursing; that no medicines were left with him and no instructions given him by the physicians on Friday evening; and that Mr. Dwight sent for him the Wednesday preceding the Friday of his (Dwight's) death, and had requested him at that interview to sit up with him on Friday night because "in an emergency he thought I was cool and would not get excited." He also admitted on cross-examination that he had stated before the Coroner's jury that Dwight said "he wanted him because he would be cool in case anything should happen."

Mr. Hull testified that shortly after 10 o'clock:

"I stationed myself in a chair near the door leading into his bed-room, and this door was partially open, and I sat there. During the time I sat there, at one time the Colonel called me, and said his head was feverish and wished me to saturate a cloth in bay rum and put it on his head, and I did so. And at another time, he called for some water and I gave him a swallow of water. After that he seemed to sleep, and before, at different times, I thought he was sleeping, but of course it was uncertain, and I did not disturb him. Along about between 11 o'clock and half-past 11, I heard him gasp for breath, as it seemed to me, and he says, 'Charley,' and called to me, and I went in to his side as quick as I could and put my hand under his head, and raised his head up and gave him some brandy; and then I ran across the hall as rapidly as I could to Mrs. Dwight's door and rapped on it very loud, and went back to the bedside again, and I think I administered brandy a second time then, and I felt of his pulse; and in a short time Mrs. Dwight came out only partially dressed, and I asked her to touch the bell for Mr. Spaulding, and she did so. In a very short time Mr. Spaulding came up there, and was followed by Mrs. Owens, Mr. Spaulding's brother, and his family, consisting of his wife and daughter."

That about fifteen minutes before he heard the gasping, Col. Dwight took a cracker from a stand near the bed and ate it. Also that he (Hull) sat in a chair, so placed in the sitting-room that he could see all of Col. Dwight's movements through the open door. He further stated that Mr. Spaulding pinched Dwight's tongue, leading to the suspicion that it was protruding.

The only other evidence at all bearing upon the events now under discussion was that given by James E. Lee, the servant who brought the hot water in which, Mrs. Owens and Mr. Hull testified, the hands of Col. Dwight were soaked after she entered the room. Mr. Lee believed that he saw Col.

[1] Attorney-General Russell, in his speech, asserted that the plaintiffs' counsel had claimed the right of putting Drs. Orton and Burr upon the stand, with the expectation that the judge would decide against them, and that then they would say to the jury that they could have explained Col. Dwight's sickness and death by the physicians who attended him, but that the court would not admit the testimony.

Dwight breathing at the rate of about four or five times a minute. Before this, however, according to the statements of both Hull and Mrs. Owens, Col. Dwight was dead.

Third. As already stated the *expert testimony on the part of the plaintiffs* was limited to a description of the lesions found in the body after death. In regard to these lesions the cross-examinations of Drs. Hyde, Burr, Chittenden, and Orton, elicited the fact that there was very little non-agreement between them and Dr. Swinburne, except in regard to the appearances upon the neck.

It was claimed by several, if not all, of these gentlemen, that the so-called indentation upon the neck was simply a crease or fold in the skin; but on cross-examination they all admitted that they had signed at the time of the autopsy, when the body was before them, without comment or protest, an official description of this crease as "a heavy indentation, extending upwards and backwards from os hyoides to right around back of neck, and on left side, below the thyroid cartilage, running upwards and backwards at an angle of about forty-five degrees."

In the manuscript notes of the autopsy there were certain erasures and interlineations. The testimony as to whether these had been made before or after signing was conflicting, but on other points there was no question as to the authenticity of the notes which bore testimony to the existence of "several small ecchymoses of skin of back and shoulders; *anterior* part of right arm, small ecchymosis." In other respects the description corresponded with that given by Dr. Swinburne in the testimony for the defence, except that the word "bloody" had been scratched over with a pen, as it occurred in the notes before "mucus," speaking in reference to the bronchial tubes; and that, instead of the lungs being said to be emphysematous, they were spoken of as "unduly inflated."

Testimony was given by Mr. Van Vradenburg, Mr. Ayres, the undertaker, and James E. Lee, in regard to the existence of a furrow around the neck shortly after death. Mr. Van Vradenburg testified that his "examination of his neck" "was close and marked," and that he was led to make this examination "on account of something that was then stirring in my [his] own mind." The nature of this "something" was not in evidence, but Mr. Van Vradenburg further stated that "it did not lead him to investigate any other part of his [Dwight's] person," nor did he examine the feet or hands.

Mr. Ayres testified that he was the undertaker who prepared Col. Dwight's body, washing and dressing him; that directly after his death there was "no crease or mark as of a rope or otherwise upon his neck." He further testified that the body was placed in an ice-box in such a way that the head was forcibly bent forward on the body, the chin resting upon the chest, and the occiput being raised, so as to bend the neck at an angle of about forty-five degrees. He gave it as his opinion that the crease, or furrow, or indentation subsequently found in the neck of Col. Dwight was produced by the elevation of the head in the ice-box, and its subsequent restoration to the normal position. Mr. James E. Lee stated that he assisted the undertaker, and the crease was not there then.

After the plaintiffs had closed the case, the defence recalled their experts, and put to them the following hypothetical questions. There was no dispute whatever as to the agreement of the conditions of these questions with the facts of the case as testified to by the medical witnesses for the plaintiffs; in the second question, the testimony of Messrs. Van Vradenburg, Ayres, and Lee in regard to the non-existence of the furrow directly after death was omitted; the medical part of the question is taken almost verbatim from the notes of the autopsy, the disputed part of these notes being omitted.

Question 1.[1] "Assuming that a man of 41 years of age, who had previously enjoyed robust health, had been complaining for about three weeks, and was found on a Saturday morning in bed, shivering, teeth chattering, surface clammy and cold, with the blood settled under his nails, and so continued from one to two hours, breaking out into a cold sweat, with a feeble, whispering voice, and that this attack passed off without fever; that the second Friday after this occurrence, having during the day been up attending to business with his lawyer, and having his beard dressed by a barber, he was left about 10 P.M. by his doctor in such a condition as to create no alarm; that at or about 11 P.M. he spoke pleasantly to his attendant, calling his attention to his manner of eating a cracker, helping himself to one from a dish near his bed, and chewing it without difficulty; that within fifteen minutes the attention of the attendant was called to such man by a gasping noise, and that this man was dead in a few minutes thereafter; that at an autopsy held within fifty-eight hours after death the liver and spleen were found to be normal, except congested, the heart nearly empty, and that there was no pigmentation anywhere; could or could not such a man have died of congestive chill, or any other form of malarial fever?"

The uniform answer to this question by the experts was that, in their opinion, he could not have so died.

Question 2. "Suppose that a man, after an obscure alleged illness of about five weeks' duration, is on a given day able to be up and transact business with his lawyer and have his beard trimmed; is left by his doctor at 10 P.M. on the same day, in such a condition as not to give any cause for alarm; and that at 11 P.M. is talking pleasantly to his attendant and eating a cracker, and in less than half an hour after is dead; and that at the autopsy, made fifty-eight hours after death, the following conditions are revealed: a heavy indentation, extending upwards and backwards from os hyoides to right around back of neck and on left side below the thyroid cartilage running upwards and backwards at an angle of about forty-five degrees. Post-mortem discoloration of posterior portion of body, several small ecchymoses of skin of back and shoulders; anterior part of right arm small ecchymosis. Thorax, lungs, and heart in natural position, except that the lungs are unduly inflated. About four ounces of serum in bottom of left pleural cavity; the same amount in right pleural cavity. Left lung one pound and three-quarters; bronchi congested and coated with mucus. Upper lobe congested and œdematous; lower lobe still more congested and œdematous.

[1] The first part of this question was based upon the testimony of Mrs. MacDonald.

Right lung two pounds; bronchi congested and coated with mucus. Upper lobe, at the apex several small fibrous nodules; rest of upper lobe congested and œdematous. Lower lobe congested and œdematous. Heart healthy; weight, fifteen ounces. Right ventricle contains a little fluid blood, not over one-half ounce; left ventricle contains little fluid blood, not over one-half ounce. Left auricle contains a little clotted blood. Stomach, at the fundus mucous membrane softened and partly destroyed by post-mortem changes. Pyloric end of stomach, mucous membrane studded with small white spots denoting chronic gastritis. Liver congested more than usual; normal color and consistence. Kidneys uniformly congested, and otherwise healthy. Epiglottis, larynx, and trachea congested and coated with mucus. Inner surface of the dura mater on the left side, chronic hemorrhagic pachymeningitis, with a small extravasation of blood on the left side, over the posterior portion of the parietal and anterior portion of occipital lobes. Pia mater of convexity normal, except discoloration over occipital lobes from blood. Brain neither congested nor anæmic, otherwise healthy. And further, that at an inquest held five months after the first autopsy, the indentation on the neck was still distinctly visible; could or not death have been produced by natural causes?"

The answer to this question was given by Drs. Porter, Swinburne, Bridges, Sherman, and Wood, who agreed in stating that it could not.

To each of these physicians the further question was put as to what in their opinion was the cause of death under the conditions named. All agreed in answering positively that death was produced by strangulation with a rope or cord.

The following question was asked in regard to the furrow:

Question 3. "Assuming that the body of a man weighing in the neighborhood of two hundred pounds, forty-one years of age, having a full, fleshy neck, about two hours after death is placed upon a board on its back, with the head raised upon a book and two pillows, and left in that position for about nine hours; and then placed in an ice-box with its head elevated at an angle of about forty-five degrees, and left there for about forty-eight hours, and then removed and placed flat on a table; is it possible that a heavy indentation, commencing near the Adam's apple, and running upward and backward at an angle of about forty-five degrees on either side to within less than two inches of meeting in the rear, could be produced by the changes in position stated?"

The negative answer which was given by the experts to whom this question was put, seems to me entirely correct. I cannot conceive how a fold or crease made by bending the neck should deserve the use of the term "heavy indentation" to describe it, and it is still more inconceivable to me that a fold, or crease, should be made in the *back of the neck* by bending the head forwards, which would necessarily stretch the parts said to be folded. Further, a crease made in the manner described would be most marked in the front of the neck where the centre of the fold would occur, whereas the indentation was not visible at this place. Moreover, the plaintiffs' experts stated that the indentation involved the subdermal adipose tissue of the sides of the neck, and it is very hard to understand how a crease made by bending the neck forward for a day or two could do this and be so deeply impressed as to remain distinctly perceptible after the body had been buried five or six months.

In concluding this statement of the case of Col. Dwight, it remains only to call attention finally to the remarkable agreement that there is in the testimony, and to the fact that there was extremely little conflict, practically no conflict at all, between the experts; that the sole contradiction of any importance was between Messrs. Van Vradenburg, Ayres, and Lee on the one hand, and the experts on the other. If the former witnesses were correct in affirming that there was no indentation in the neck directly after death, the theory of strangulation with a cord drops; although it would still be proved by the internal appearances that death was caused by mechanical asphyxia produced in some other way than by a cord. It must be remembered that it is a well-known fact that in suicidal hanging, in which the suspension has been only for a few minutes, the cord-mark acquires its color only some hours after death, and then becomes more prominent; that Col. Dwight was a heavily bearded man, and that his beard might have hid the fresh indentation from an unsuspecting undertaker. If, finally, it is considered that there is an absolute conflict of testimony, I must leave to the judgment of my readers the probability of the truth being upon the side of Van Vradenburg and the undertaker, with his assistant, or on that of Drs. Swinburne, Sherman, and Bridges, who especially testified to the medico-legal facts in the case, and were corroborated in almost every particular by the notes written at the autopsy and signed by each of the fifteen doctors there present, and also by the evidence of two laymen, Freeman and Hitchcock, as to the appearance of the indentation at the second autopsy.

A CASE OF SEVERE HEMORRHAGE FROM THE KIDNEY, SUCCESSFULLY TREATED BY AN UNUSUAL REMEDY.

BY S. J. RADCLIFFE, M.D.,
OF WASHINGTON, D. C.

THE following unique case of hæmaturia, due to hemorrhage from the right kidney, I think is worthy of record. It shows how formidable such cases may appear, and at the same time how simple, and yet how effective the remedy we have at command to relieve it, as was evinced in this case.

August 2, 1883, I was called to see Miss S., a spare, delicate lady, about twenty-five years of age, a former resident of Louisiana. She had suffered from malarial disorders, such as remittent and intermittent fevers. Her mother died of heart disease, subsequently to rheumatic fever, and had suffered from hemorrhage from the lungs and nose (hæmoptysis and epistaxis), due, probably, to a hemorrhagic diathesis. Other family history unimportant.

Previously to my seeing her she had spent two weeks at Oakland, Maryland, where the temperature is invariably low and subject to sudden changes, and while there was attacked with hæmaturia of

unusual and alarming severity, passing almost pure blood, on account of which, by advice of her attending physician, she returned to Washington.

She had had such an attack, though slighter, two years before; and one year before her feet swelled, and she had another slight attack, lasting a few days, four months before.

At the time of my visit she was a little flushed; temperature 99.5°; pulse 100, weak and small; respiration slightly hurried, but regular; bowels active, and menstruation normal; heart sounds and rhythm normal.

Her general appearance was feeble; she complained of lassitude, and of an aching pain in the right side, in the region of her right kidney, paroxysmal in character, causing during the paroxysms much suffering, and attended by considerable nausea, and she was passing during the twenty-four hours from thirty to forty ounces of thick, muddy, dark, brownish-red urine, uniform in color throughout, quite fluid at top, but forming a thick, partly coagulated, brighter colored deposit or mass at the bottom of the vessel, and showed here and there more or less flaky or shreddy particles.

During the paroxysms of pain and nausea, which at times were severe, the discharge of bloody urine was less, and a little varied in color, on account, probably, of obstruction of the pelvis of the right kidney, and the flow of urine coming mainly from the left kidney. In every other respect the discharge was the same, and fully proved its hemorrhagic nature. She had no pain over the bladder region, or tenderness on pressure, and efforts at micturition were not attended by discomfort or pain, or only occasionally so, as the effort in passing the urine was not great, and not generally urgent. The urine seemed to accumulate so slowly in the bladder that she was not cognizant of any desire to micturate until the viscus was sufficiently full, when she would void it not oftener than three or four times in the twenty-four hours, and it always came in the thick, muddy stream as found in the vessel.

Under the microscope the field was crowded with red blood-corpuscles, some few epithelial scales from the bladder, and a few tube casts, some studded with blood corpuscles. It was nearly neutral or alkaline in reaction. With heat there was thrown down a dark brownish albuminous deposit of about two-thirds, light and frothy at top, and denser below. The fluid on standing, as passed from the bladder, in a test-tube, showed a sediment of one-third, of dark brownish color, the clear portion above being dark claret. The specific gravity was 1.028. By agitating it in the vessel the deposit would partly mix with the more fluid portion, showing no firm clot, but on settling again would flatten out and become smooth, and fibrinous in appearance. No moulds of the pelvis of the kidney or ureter were discovered by an ordinarily careful examination, nor were there any clots passed large enough to obstruct the passage through the urethra, or other parts, sufficiently formed to indicate their source.

This was the condition of the case when first examined, and which continued daily, with very little deviation or change, and constituted its history up to the nineteenth day. A nearly equal quantity of bloody urine was passed each day, having the same general characters, and the hemorrhage continued with such disheartening persistency, the debility and feebleness becoming more and more pronounced, the drain upon her system manifesting itself hourly by the feeble action of the heart, the impending syncope being so great as to urge the necessity of keeping her bed, and assume absolutely the recumbent position, that from hopefulness the patient lost all courage, and began to be very desponding and to regard the future as very gloomy. The pulse-temperature rate was almost always in direct ratio, and a little above normal; the ratio being about 90: 99 *vel* 100: 99.5, and seemed to be about the same morning and evening, and exhibited no irregularity, apyrexia, or exacerbation. The condition was apparently the result of nervous irritability or debility rather than of febrile action.

Her attending physician at Oakland had prescribed gallic acid in large doses, but with no favorable result. I continued the gallic acid alone, and in various combinations for several days, combining the acid with quinine, with ergot, with sulphuric acid, and with a menstruum of cinnamon-water, with opium in several forms added, with like results. I prescribed also tannic acid, sugar of lead and opium, fluid extract of ergot, infusion of buchu and matico, muriated tincture of iron, and this with quinine; extract of logwood, extract hamamelis, with ice externally and internally, counter-irritation by sinapisms and blister over the region of the right kidney, and enjoined quiet, absolute rest in bed with the head low, and every means to allay excitement or agitation of mind or of the nervous system, besides a nourishing diet of milk and beef extract. This treatment was continued until the 21st of August—the nineteenth day of treatment—giving each prescription ample time to operate, and, with the exception of the fluid extract of hamamelis—which seemed to check or lessen the hemorrhage for from twenty-four to forty-eight hours—it appeared as if I might as well have given her so much cold water.

Having gone through this list of approved remedies, in addition to the counter-irritation already set up, and continued, without any real improvement in the case, as a last resort, on theoretical grounds, I prescribed Rockbridge alum water, having prescribed it before with benefit in chronic discharges, as in serous diarrhœa and in bronchorrhœa. I directed it to be taken in champagne-glassful draughts every three hours, to be increased in quantity if found necessary. After the third glass, really, its beneficial effects were manifested. On the second day, the improvement was still more observable. The urine was lighter in color, only smoky, and but little sediment. On the third day, a little return of hemorrhage, with some clots, and pain in the right side. On the fourth day, the urine was nearly free of blood corpuscles; no smokiness; of a dark amber color; only a trace of albumen, slightly milky by heat. On the fifth day, the urine was nearly normal in color and quantity, only a scattered corpuscle here and there, and but a faint trace of albumen. On the sixth day, the urine was normal in

quantity and quality, the color light amber and clear, the sp. gr. 1.018; there was no deposit, or blood-corpuscles or casts. On the 28th of August, one week after beginning the use of the alum water, though quite weak and pale, her appetite had returned; she was able to get on the lounge, and convalescence seemed to have fully set in.

On the 16th September, she had been out riding twice; her appetite improved, and she was cheerful. Her pulse was still quicker than normal, and weak, and she had emaciated considerably, but had had no return of the hemorrhage, and she considered herself safe from that while she took the water, which I ordered continued indefinitely.

At the present time, she is able to take walking exercise to a limited extent, and has gained in flesh and vigor; at the same time, she shows a condition of marked anæmia and of impaired health, which may or may not be overcome in time.

The object I have in view in reporting this case is mainly to show how promptly a natural mineral water relieved it after other usually effective and approved remedies had totally failed to do so, and not to discuss the pathological condition lying behind it, as that may be veiled in uncertainty. The condition may have been that of anæmia, of progressive anæmia, or anæmia or blood-poison of malarial origin, in a subject fully susceptible to the malarial influence, or a predisposition from a hemorrhagic diathesis, all or either of which would be a proper diagnosis. There was no malignant trouble discernible either of the kidneys or bladder, and it could hardly be called a case of simple hyperæmia, or of acute or chronic Bright's disease, or scorbutus or purpura. The hemorrhage, considered as a symptom, was very formidable, and I think such a condition is seldom encountered, and I can believe now that there may be instances where such a hemorrhage might prove fatal.

In the analysis of Rockbridge Alum Water Spring, No. 4, made by Prof. M. B. Hardin, of the University of Virginia, one gallon of 231 cubic inches contained:

Arsenic,	Trace
Antimony,	Trace
Lead Sulphate,	Trace
Copper Sulphate,	0.10370

Specific gravity, 1.10174.

MEDICAL PROGRESS.

CHLORAL POISONING.—DR. PAOLO ROSSI publishes a case of poisoning by ʒvij of chloral hydrate, which is chiefly interesting on account of the recovery of the patient.

The patient was a young man, aged twenty-five, who took ʒvij of chloral hydrate dissolved in water, half an hour after eating. About half an hour afterward ʒj of cherry-laurel water was given. Two hours after the ingestion of the drug the patient was seen by Dr. Rossi. At that time the patient had the appearance of one attacked by severe cerebral hemorrhage. The face was congested, the respiration stertorous and 32 per minute, pulse small and 132. The temperature was normal. Cutaneous anæsthesia; muscular relaxation was complete; the pupils were contracted, but mobile. There was no vomiting or purging. The cherry-laurel water had had no effect.

Vomiting was produced by titillation of the fauces. Twenty-eight sinapisms were applied, and ♏xv of ether were injected hypodermatically; an ice-bag was applied to the head, and a clyster of fʒvj of alcohol was administered. About two hours afterward he began to move his arms. Little by little he began to move his body, and finally sat up. On the next day a large dose of citrate of magnesia was administered, which produced four or five evacuations.—*Gaz. degli Ospitali*, October 10, 1883.

HELENINE IN DISEASES OF THE RESPIRATORY APPARATUS.—DR. F. VALENZUELA reports a number of cases of pulmonary affections in which helenine has given very good results.

1. A man, æt. 46, had chronic broncho-pneumonia which had resisted all the usual remedies. Treatment by helenine was commenced to the exclusion of other remedies. In fifteen days there was a very decided amelioration of the disease and of the general health.

2. Male, æt. 36. Pulmonary tuberculosis was diagnosed. The patient had a tuberculous spot at the summit of each lung, and was much troubled by a persistent cough and bloody expectoration. Helenine was given in doses of gr. one-sixth in pill, ten every day, for two weeks. At the end of that time, there was very marked improvement in the physical signs and general symptoms.

In private practice, Dr. Valenzuela has excellent results from helenine. The best effects from it are obtained in whooping-cough. It may be administered internally or by inhalation: the first method is always sufficient. It has a tonic effect on the general system, increasing the appetite, and seemingly aiding digestion.—*Bull. Gén. de Thérap.*, December 15, 1883.

RUPTURE OF THE VESSELS OF THE UMBILICAL CORD.—This case, both rare and interesting, is reported by the late DR. RIVET in the *Archives de Tocologie*, September, 1883. It was observed in the service of Dr. Boudin at the Charité.

The case was that of a woman pregnant with twins. One child was delivered without accident, and the second, enveloped in an amniotic sac, presented. The membranes did not rupture until the head presented at the vulva, when a jet of blood was seen to escape from the free edge of the ruptured sac. Delivery was effected, and the following state of things found: There were two distinct placentæ. Into the first the cord was inserted marginally, in the second centrally. The rupture had taken place at the entrance of the vessels, and the two arteries and the vein were ruptured. This explained the escape of blood when the second sac was ruptured. The second child was born apparently dead, but was resuscitated.—*Bull. Gén. de Thérap.*, Nov. 30, 1883.

TUMOR OF THE ANTERIOR MEDIASTINUM.—PROF. PIETRO BURRESI reports the following case:

A. M., æt. thirty-five years, a robust man, of healthy family, and with no history of hereditary disease. In infancy, and up to the age of eighteen years, he had suffered with blennorrhagia. He had an attack of typhoid fever at the age of twenty-one, and was ninety-three days convalescing. Three years later, he had an ulcer on the glans, which did not entirely cicatrize for fourteen months. There was no inguinal adenitis during the period of this ulcer, nor was it followed by syphilitic manifestations of any kind. At the age of twenty-five years, he had attacks of malarial fever. Since that time he has not been well.

In 1880 he began to complain of various pains, which he described as rheumatic, and especially of a pain situated in the anterior superior part of the chest. In 1882, the pain having increased, he entered a hospital, having incessant cough and some oppression of respiration. In April, 1883, the fever returned, accompanied by a dry cough. The pain extended from the left subclavicular fossa to the sternum and precordial region, and extended down the left arm. In the latter part of April, tumefaction of the face and cyanosis began to appear, which gradually increased, and extended to the neck and the whole upper part of the chest, with a sense of constriction, dysphagia, and continued oppression of respiration. Slight epistaxis occurred early in May. The skin of the upper part of the body became bluish, the arms and forearms being also involved. The respiration was irregular and labored. The cardiac impulse was weak, but distinctly appreciable in the fifth intercostal space, and extended to the parasternal line. The left radial pulse was somewhat smaller than the right. These symptoms and the physical signs common in such cases increased, and the patient went from bad to worse, and died on May 30, 1883.

Autopsy.—On opening the chest there was found adherent to all the surrounding structures, and completely occupying the anterior mediastinum, a tumor extending from the base of the neck to the diaphragm. It was adherent to the costal cartilages and sternum on both sides, and to the costal pleura, the left lung being also invaded to a considerable extent. The tumor was of ovoid form, measuring in its long diameter about eight inches, and about five and a half inches in thickness. Microscopical examination by Dr. Banti showed it to be a round-celled sarcoma.

The left lung was invaded for about two-thirds its whole extent, the other third being in a state of atelectasis from compression. The right lobe was a little smaller than usual, and atelectatic in the upper part. The anterior portion of the external surface of the pericardium was invaded by the neoplasm, the auriculo-ventricular groove being filled. The aorta was embraced by the tumor in its whole ascending portion and arch, the origin of the innominate and corresponding common carotid being also involved, as was a part of the left subclavian artery. The right subclavian was completely embraced by the tumor in its first part, and constricted. The superior vena cava was compressed, as was the pulmonary artery. [For other cases, with account of symptoms and autopsies, see the *Am. Journ. of the Med. Sciences*, Jan. 1884, p. 271.]—*Lo Sperimentale*, Nov. 1883.

TREATMENT OF PHAGEDÆNIC CHANCRE WITH PYROGALLIC ACID.—M. VIDAL, Surgeon to the Hôpital Saint-Louis, has called the attention of the Academy of Medicine to the treatment of phagedænic chancre, which he has used for several years. The following are the formulæ usually employed by him: Pyrogallic acid one part, vaseline four parts; another, which has given excellent results, is pyrogallic acid and starch each one part, vaseline three parts. For anfractuous sores, with many prolongations, he uses the following: Pyrogallic acid one part, powdered starch four parts. This powder is blown into the various parts of the sore by means of a powder-blower. The dressings to be renewed twice a day. Only a fresh preparation should be used, kept in a closely stoppered bottle.—*Bull. Gén. de Thérap.*, November 30, 1883.

EXPERIMENTAL DIPHTHERIA.—A series of valuable experiments and investigations upon the subject of diphtheria have lately been published in Leipsic by DR. O. HEUBNER, and reviewed in the *Centralblatt für klinische Medicin*, No. 43, 1883. Following the lines previously traced by Treitz, Oertel, Weigert, and others, who had already succeeded in the artificial production of false membranes upon mucous surfaces, he made a series of experiments with the view of producing such artificial membranes in a manner more resembling the natural processes of disease than had before been attempted. By modifying the blood supply of a portion of the mucous membrane of the bladder he succeeded in producing a form of epithelial necrosis with the formation of a definite membrane in every way corresponding to that found in diphtheria. By occluding a large branch of an artery for several hours, and then restoring the circulation, he found that the following changes were induced: Inflammatory œdema with detachment and vacuolation of the epithelial cells, the mucous membrane becoming surrounded with an albuminous exudation which speedily coagulated. In about ten hours parts of the tissue thus affected showed signs of necrosis; in forty-eight hours these parts became still further decolorized, and stood out as yellowish-white patches upon the surface of the mucous membrane. On the edges of these patches the surrounding healthy

epithelium was observed to be thickly infiltrated with blood corpuscles. This coagulation-necrosis advanced steadily, gradually attacking the whole mucous membrane of the bladder, the hemorrhagic infiltration advancing with it. It seems more than probable that the production of simple membranous croup in the human subject may be due to a similar temporary arrest of circulation from spasmodic contraction of vessels. But from Heubner's experiments it must be concluded that the immediate cause of the local affection of the mucous membrane in diphtheria must be temporary arrest and subsequent restoration of the circulation. This, however, is only a small part of the pathology of the disease. By injecting into the circulation portions of genuine diphtheritic membrane, it was found that the poison concentrated itself especially within the artificially produced patches of membrane, and injections made with this latter membrane were found to be far more fatal in their results than were those made with the first membrane, produced by the natural processes. Further, it was found that injections of apparently healthy membrane in the neighborhood produced no result whatever. That an active poison must be at work in these cases is almost certain; but the question of its nature remains still unsettled. Whether it must be ranked with the class of septic poisons, of which Koch has enumerated a series, or whether a genuine diphtheritic poison exists distinct from these, cannot at present be proved, although Heubner's experiments have fairly opened a way which may eventually lead to its discovery.—*Med. Times and Gaz.*, December 1, 1883.

METHOD OF HASTENING THE ANÆSTHETIC ACTION OF THE ETHER SPRAY.—The ether spray is employed frequently at the Hôpital St. Louis in Paris for the production of local anæsthesia. A little device, first indicated by Dr. Letamendi, of Barcelona, but not hitherto utilized in practice, is employed by Dr. Vidal to shorten the duration of the process of congelation. It consists in making a slight prick with a needle at the point upon which the spray is directed, at the moment when the skin assumes a purplish hue, and when the ether, commencing to solidify, assumes an oily consistency. The little puncture made at this time excites a reflex constrictive action of the vaso-motor nerves, the blood is driven from the part, and the skin becomes white. Another method of hastening the process consists in placing little wads of lint about the part, thus increasing the surface of evaporation.—*Practitioner*, Dec. 1883.

TURPENTINE IN DIPHTHERIA.—According to DR. SATLOW, spirits of turpentine, administered internally, gives superior results to the usually employed remedies for diphtheria. Its value was accidentally discovered by Bosse, of Domnau, a spoonful having been given by mistake to an infant suffering with diphtheria. Satlow first used it in teaspoonful doses, in March, 1881, in the case of an infant in immediate danger of death. The result was excellent. Two other trials, followed by equally favorable results, convinced him of the good effects of this substance, and of its harmlessness in large doses.

He has now used turpentine in forty-three cases, and has had only one death, the result of paralysis of the heart in a case already convalescent. Of the forty-two cases of recovery, three had diphtheria of the larynx and nose, seven had albuminuria, and one had hæmaturia. There was paralysis in four, and strangury without albuminuria in some others.

Satlow uses, when possible, the freshly distilled spirit in the following doses: For children, up to the age of nine years, he gives a coffeespoonful; for children above the age of nine, two coffeespoonsful, and for adults a dessertspoonful during the day, always giving a quantity of milk or wine after the dose. The appearance of strangury is an indication for the interruption of the treatment, but not for its cessation.

The tolerance of patients for the medicine is variable. After taking it they sometimes complain of burning pain in the throat, a sense of pressure in the stómach, and sometimes vomit. The addition of ether ℥xv to spirits of turpentine f℥ss will often prevent the vomiting. The greater part of the medicine is eliminated with the feces and urine, the latter having the peculiar violet odor so well known.

The action of the remedy is manifested by swelling and softening of the membranes, which become transparent and finally disappear with the inflammatory phenomena, the painful deglutition, and the ganglionic swelling. The complete effect is only manifested on the third or fourth day in grave cases. The efficacy of turpentine depends on its antimycotic properties, Koch having shown that a solution of one to seventy-five thousand will arrest the development of charbon spores. —*Centralbl. f. die gesammt. Thérap.*, September, 1883.

MOSS AS A DRESSING.—Turf has been sometimes used topically as a dressing for suppurating wounds. Its absorptive property is due in a great measure to the moss which it contains. M. NAGEDORN employs fresh moss in the same manner, dried at a temperature of 105° or 110° C. in a stove, and placed in pillows. In using this with the antiseptic dressing, a small cushion of gauze, impregnated with a solution of corrosive sublimate, is first applied; then a larger cushion, to cover the field of operation, and then a third still larger, the whole being maintained by bandages. This dressing is sprinkled, as necessary, with an antiseptic fluid.—*Journal de Méd. de Paris*, December 15, 1883.

THERAPEUTICS OF IODOFORM.—FRUEHWALD reports twenty-six cases of diphtheria which were treated with iodoform in Prof. Widerhofer's clinic at Vienna. It was employed by insufflation, or by dusting; also by applications of a ten per cent. iodoform-ether solution. In some cases, especially in mild ones, there was an early expulsion of the diphtheritic deposit. In others, particularly in severe cases, neither a local nor a general effect was accomplished. Also in one case of a diphtheritic wound, iodoform proved useful as a topical application. In another case of diphtheritic conjunctivitis the effect was less marked. In ten of these twenty-six cases the patients died. Iodoform also proved to be very useful in the treatment of stomatitis ulcerosa, the affected parts being brushed over, once daily, with cotton which had been dipped in iodoform powder. Gelatine bougies containing fifty per cent. of iodoform, six centimetres long, and from three to five millimetres in diameter, were, in certain cases, remarkably effective in vulvo-vaginitis. Unpleasant results were never observed. —*Archives of Pediatrics*, January, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 12, 1884.

SUDDEN DEATH IN DIPHTHERIA.

THE accidents which may occur in any case of diphtheria must be apprehended until health is fully restored. The most formidable of these accidents is sudden death. In our last issue there is reported an interesting example of such an unexpected termination of a case, severe indeed, but by no means remarkable for the extent and variety of the lesions. Other instances have appeared from time to time in our columns, and in the pages of our contemporaries. It may, therefore, be useful to place before our readers a survey of the conditions which result in sudden death in some cases of diphtheria.

It is first to be noted that many of these suddenly fatal cases occur during the period of supposed convalescence. They are the more to be dreaded in that an early restoration to health is expected by the friends, and confidently predicted by the physician. Very often the end comes when the patient, raised to the erect posture, is in the act of taking food. Failure of the heart is supposed to be the cause of death, when apnœa has been induced by closure of the glottis by food or drink. This may occur in mild cases of diphtheria. Donders was amongst the first, if not the very first, to show that paralysis of the muscles concerned in deglutition—especially the pharyngeal muscles—is a not uncommon condition in simple cases, and often precedes all other symptoms of diphtheritic paralysis. The alimentary bolus not being properly grasped, and the entrance to the larynx insensitive, articles of food and drink may readily drop into the chink of the glottis. As respiration is apt to be hurried, and the need of air imperious, an ill-timed inspiration may precipitate the catastrophe. The position of the epiglottis is another element in the sources of danger. Not properly supported, and therefore much inclined downwards, particles of food accumulate behind it, and thus, suddenly, by a strong inspiration, it is brought down on the larynx as a valve, which is the more firmly fixed there the stronger the inspiratory efforts. Thus, in several modes, may life be suddenly extinguished by closure of the glottis. Less rapidly may the same mechanism determine a fatal result by setting up a traumatic pneumonia. Small particles passing the chink of the glottis enter the lungs, and excite a peculiar and rapidly fatal inflammation.

Simultaneously with the faucial paralysis, the respiratory muscles may be affected, and although this usually induces a rapid congestion of the lungs, it may be a cause of sudden death. Without any pronounced symptoms, besides some embarrassment of breathing, which may be largely subjective, the respiratory muscles may suddenly fail and death ensue with apnœa. These modes of sudden death, are, however, far less common than that due to paralysis of the heart.

It is quite foreign to our purpose to consider the various lesions of the heart which may occur in the course of diphtheria. We are here concerned with those changes which are common causes of sudden death. These are chiefly two: myocarditis, or parenchymatous degeneration of the muscular tissue, and paresis of the cardiac motor ganglia. To the changes of the former may be added the effects of migrating micrococci colonies, and the latter is a part of a general change in the ganglia of the sympathetic. Damaged in respect to one or both of these parts, the heart may still be capable of carrying on its work when the body is recumbent. The fatal paralysis occurs when a change to the upright position requires the organ to put forth more vigorous efforts. Either the ganglia cannot produce the needed force, or the muscles prove unequal to the sudden strain, or both fail simultaneously. Quick arrest of the heart's action may also result from heart-clot. Weakness of the muscular tissue of the organ, and consequent feeble contractions, is an important factor in these cases, but the most influential condition is hyperinosis of the blood. Ulcerative endocarditis, in which, also, migrating micrococci colonies may play a part, favors coagulation of the blood. Although heart-clot is popularly assigned a high place as a cause of sudden death in diphtheria, it is, probably, very infrequent.

Another mode of sudden death—cerebral—there is reason to believe, does happen more frequently than is now supposed. We refer to cerebral hemorrhage and the so-called serous apoplexy, both accidents which may attend on albuminuria. In

making this statement we are not unmindful of the convulsive phenomena, and the direct interference with the respiratory centre, which may be due to the cerebral changes consecutive to albuminuria.

The means to obviate the danger of sudden death in diphtheria, must be largely prophylactic. The necessity for the careful administration of food needs hardly to be stated. In the cases of paralysis involving the apparatus of deglutition, the use of the feeding-pump of Débove might prove valuable. In the condition of anæsthesia present in these cases, the operator passing the stomach-tube should not fail to remember the unfortunate experience of that London surgeon, who, supposing his tube had reached the stomach, was found after death to have filled his patient's lungs with the chalk-mixture intended for the former organ.

The measures necessary to preserve the strength of the heart, to be properly stated, would require a dissertation on the treatment of diphtheria. We should not close, however, without a word of caution in regard to the use of digitalis. A remedy like this, which raises the vascular tension and increases the inhibitory action of the pneumogastric, may impose a fatal burden on the heart's movements. The heart is to be strengthened rather by those means which promote digestion and assimilation.

THE TRANSPLANTATION OF CARCINOMA AND SARCOMA.

In a contribution to the *Revue de Chirurgie*, No. 11, 1883, M. Nicaise discusses the subject of the inoculability of malignant growths, and arrives at some conclusions which are at variance with the published experiments of not a few observers. Although it is quite true that attempts to reproduce carcinoma and sarcoma by means of inoculation under the skin with the juice of these morbid growths, by its injection into the veins, or by inserting particles of the fresh tumor into a recent wound, usually fail, it is none the less true that a sufficient number of positive results have been obtained to demonstrate conclusively that these products may be transmitted in the ways just mentioned.

In summing up the results of his labors, which were confined solely to an examination of the literature of the subject, the author formulates the following conclusions: First, that the transmissibility of cancer from man to animals has not been demonstrated; and, secondly, that the same statement holds good for the transmissibility of cancer from an animal to an animal of the same species. Bearing in mind that he employs the term cancer as the substantial equivalent of sarcoma and carcinoma, we think that we will be able to show, in the cause of scientific inquiry, that both propositions are groundless, possibly from an insufficient knowledge of the entire field of experimentation.

That the malignant growths may be transmitted from man to the lower animals has been demonstrated by the following observers: Lebert and Follin injected from sixty to seventy grammes of the juice of carcinoma of the breast into the jugular vein of a dog. On the death of the animal, at the expiration of two weeks, a number of carcinomatous nodules were found in the heart, and the liver was the seat of miliary carcinosis. Professor Klencke, of Braunschweig, inoculated the conjunctiva and lachrymal gland of an old horse with the juice of a pigmented sarcoma of the orbit. A black spot remained in the conjunctiva, and, at the end of sixteen weeks, the entire gland was converted into a similar growth, which produced protrusion of the globe. Langenbeck injected fresh carcinomatous juice into the femoral vein of a dog. The animal was killed in three months, when three flat nodes were detected in the lung, which Virchow pronounced to be carcinomatous. O. Weber injected the juice of a medullary cancer into the femoral vein of a dog, and inserted particles of the tumor under the skin. At the end of sixteen days a large growth, possessing the same structure, had developed under the skin. Lebert and Wyss inserted the juice of a melanotic sarcoma under the skin of a rabbit; on death, in two months and a half, a tuberous pigmented mass, two inches square, had formed. Finally, Mr. Wile succeeded in transmitting carcinoma from man to two dogs by inserting grafts under the skin.

The positive results obtained from subcutaneous grafting in animals of the same species, are, so far as we are aware, only three in number. Noivinsky inserted particles of medullary carcinoma of the nose of a dog into fresh wounds made in the backs of other dogs. Two out of the fifteen developed carcinoma at the point of inoculation. The third case occurred to Goujon, who succeeded in grafting a guinea-pig with epithelial carcinoma derived from another guinea-pig.

In connection with this subject, we may be permitted to refer to a case which proves the transmissibility of medullary sarcoma from an inferior animal to man, and which may be found in the *Wiener medizinische Jahrbücher*, Bd. 2, p. 162, 1862. A subcutaneous recurrent encephaloid sarcoma behind the scapula of an ox was incised on account of deceptive fluctuation, and gave exit to a sanious discharge. The wife of the owner, aged twenty-three years, cleansed the part many times, there being a wound on the outer side of the fourth finger of her right hand. In a few days a small warty excrescence was noticed at the site of the lesion, which had attained a diameter of three-fifths of an inch in one month,

was the seat of burning pain, and was covered with a grayish-white pellicle. Dr. Kuhn, of Niederbronn, finding it to be a sarcoma, destroyed it with the Vienna paste, and there was no recurrence in three months.

In the preceding paragraphs we have briefly referred to seven examples of the transferrence of malignant growths from man to the lower animals, in three by the injection of the juice into the veins, in two by the insertion of the juice beneath the skin, and in two by grafting portions of the tumor into recent wounds. In three examples, moreover, positive results were obtained by grafting from one animal to another of the same species, and in one case the juice of a sarcoma of a bullock set up a similar disease in the human subject. These positive results sustain, therefore, the view expressed in the second paragraph of this criticism, namely, that the conclusions of Nicaise are erroneous.

In a clinical lecture delivered during the current year, Dr. T. G. Thomas stated that there is great danger of propagating carcinoma by means of sexual intercourse, and that repeated instances of cancer of the penis being contracted in this way are on record. In the *Weekly Medical Review* for October, he modifies these assertions, which he cannot sustain, either from personal experience, or a knowledge of the observations of others, and remarks that he has met with only one example of carcinoma of the penis which he thought had this origin.

Following up this subject, Dr. Paul F. Mundé addressed letters to, and received answers from, Satterthwaite, Welsh, Weir, and Wyeth, of New York; Czerny, of Heidelberg; and Billroth, of Vienna, which may be found in the *New York Medical Journal* for October 27, and the outcome of which is that there is not a single authenticated case on record of inoculation of the penis by a carcinoma of the uterus. Such an occurrence is barely possible under favorable circumstances, and is worthy of further investigation. However this may be, there is no evidence whatever of the heteroinoculability of malignant growths in the human subject.

THE RADICAL CURE OF UMBILICAL HERNIA.

IN the *British Medical Journal*, for December 8th, MR. LAWSON TAIT makes a preliminary note of his practice in exomphalus. In eleven cases he has opened the sac, freed all adhesions, reduced the intestine, removed redundant and irreducible omentum, pared the edges of the ring, and stitched them together with a permanent, continuous silk thread. All of the patients recovered, and in three, in which the subsequent history could be followed, the cure was assured after eleven, eight, and five years, respectively.

This operation, thus briefly described, is well worthy of general acceptance. The superstitions regarding opening the cavity of the peritoneum have disappeared, and the danger on this score may be disregarded. What is known as the subcutaneous operation of closing the ring is open to the very serious objection of the danger of wounding the small loop of the intestine which is almost invariably present in the sac. Even if this were not the case, the omentum, which is, as a rule, adherent to the inner surface of the sac, is an insuperable bar to the permanent closure of the ring.

BACKBITING—A SERMON.

"SPEAK as you think, be what you are, pay your debts of all kinds," says Emerson; but the sage of Concord had the gift of an amiable spirit which could see no ill in his neighbors, and had only kindly feelings for all mankind. Thus provided, any one may be trusted to have his say, when the spirit of talk moves him. Most of mankind, however, need to be muzzled, or, if permitted to utter their thoughts, should have license only for the matured expression of kindly feelings.

Of all men, physicians owe it to themselves to be considerate of each other. The doctor lives before the public eye, and is the subject of unstinted praise by friends, of unlimited blame by enemies. So often must the termination of a case be adverse to the hopes and wishes of the friends and relatives, that the physician frequently receives a larger measure of suspicion and distrust, if not actual blame, than he does of just appreciation. Indeed, the best and wisest men in the medical profession, although bound to their patients by the closest ties, and rated amongst the highest for integrity, learning, and skill, are sometimes cruelly slandered, and by those from whom they have a right to expect the warmest gratitude. When the yearly balance is struck between benefits received and injuries borne, there may be slim reasons for congratulation. Should not doctors, therefore, be tolerant of each other, forbearing, and generous?

Personal qualities and peculiarities, habits, professional aims and methods, are criticised by a doctor's friends, and condemned by his enemies. The avenues to professional distinctions are beset with thorns and pit-falls; the distinctions are few and of small relative value; the competition is keen, and the spirit of it, if outwardly decorous, is oftentimes beneath marked by rancor. The candidate for place is lucky, indeed, if he comes out of a contest with a whole reputation. If a man succeed in creating an excellent position by severe and unremitting attention to all the details of a medical career, those less fortunate, be-

cause less active, are too apt to attribute the success to unworthy methods, and the failures to the exercise of unpopular virtues.

If no purpose is to be served by it, evil-speaking is indulged in, sometimes, for the mere pleasure that it affords. There are some people who always feel badly when a colleague does a creditable thing, and are correspondingly pleased when he comes to grief in any way. When failure occurs, or some evil act comes to light, under a hypocritical pretence of sorrow lurks an unctuous satisfaction. The best of us, poor creatures that we are, do not have that regret for the deep misfortunes of our friends that we give to the smallest disappointment of our own.

Probably, after all, the greatest wrongs done to our medical friends are perpetrated in the trivialities of ordinary gossip. We are so fond of a joke that tells against a neighbor—that does not hurt him too much, that makes him but a little ridiculous and that lowers him somewhat from our professional and social eminence. We are loath to do him any hurt, but would gladly take down his conceit a little, strictly for his own good. But a joke may contain a stigma that lasts. Give a dog a bad name, and hang him, is an old adage. Make a doctor ridiculous, and his best friends feel a little self-apprehensive in his company. What is fun to the boys is death to the frogs.

At this resolution-forming period it were well to have done with evil-speaking of our fellows. The remedy for the evil of backbiting is older than our oldest medical work; it is contained in some formula of the most ancient religions; it is the often-quoted but too-little practised Golden Rule, expressed in its most compendious form, "Do as we would be done by."

AN ENGLISHMAN'S OPINION OF SOME AMERICAN WORK.

In a recent "Address on the place of Literature in Medicine," Dr. Cullingworth, of Manchester, referred to two monographs as specimens of that kind of literary workmanship of the first order. One of these is Dr. Bowditch's paper on "Diaphragmatic Hernia," and the other is Dr. Read's "History and Treatment of Placenta Prævia."

Dr. Bowditch is too well known to require any explanations regarding his history and place in the medical profession. Dr. Cullingworth is mistaken, however, in assigning Dr. Read to Philadelphia, and we observe that some of our contemporaries repeat his error. His essay was, it is true, published in that city, but Dr. Read is a resident of Boston. We learn from *The Medical Register for New England*, that he was graduated A.B. from Dartmouth in 1839, and M.D. from Harvard College, in 1842. Beside this essay on "Placenta Prævia," which Dr. Cullingworth regards as a model of its kind, Dr. Read has also contributed to The American Journal of the Medical Sciences for 1858, a paper on "The Influence of the Placenta on the Development of the Uterus during Pregnancy," and in the same journal for 1861, another paper "On the Formation of Knots in the Umbilical Cord." Notwithstanding the good work which Dr. Read has done, he is probably less known to the American medical public than some far inferior writers. Now, that he is honored by foreign notice, his colleagues on this side of the water will begin to appreciate his merit. Otherwise he had gone to his grave "Unwept, unhonored, and unsung."

In further illustration of the place which the profession of this country is surely attaining in medical literature, we may mention that Dr. Cullingworth quotes freely from Dr. Billings's London International Congress address, which he designates as "admirable."

LUXATIONS OCCURRING SUDDENLY DURING THE COURSE OF GRAVE FEVERS.

At a recent meeting of the Société de Chirurgie de Paris, recorded in the *Gazette Hebdomadaire*, No. 48, M. Verneuil made an important addition to the literature of pathological dislocations, when he narrated seven examples of these accidents occurring during the course of acute articular rheumatism. In addition to his own personal observations, he reported one case from the practice of Marjolin, and in the discussion which followed, Delens added one case, and Lannelongue described two cases which occurred during the progress of typhoid fever and traumatic meningitis.

The first case of Verneuil, which may serve as a type of the remainder, was that of a girl, ten years of age, who was attacked with acute general rheumatism, which soon became localized in the left lower extremity, during convalescence from typhoid fever. The temperature was high, the pain intolerable, and the member assumed a vicious position. On the twelfth day, the suffering suddenly ceased, the limb was shortened, flexed, adducted, and rotated inwards, and the head of the femur rested on the dorsum of the ilium. Reduction was speedily effected under chloroform, and the limb was secured in Bonnet's splint.

Of the eleven cases, the hip was luxated in nine, and the knee was subluxated in two. In eight examples, the accident occurred during the course of rheumatism, in two during the course of typhoid fever, and in one during the course of traumatic meningitis. Eight of the patients were children of from five to eight years of age, and in not a single one was there any evidence of inflammatory changes

in the articular extremities of the bones. The accident is caused by the sudden and vigorous contraction of the flexors of the joints, their antagonists, the extensors, being paralyzed and atrophied, and its occurrence is favored by the flexed state of the joints, and, possibly, by the loss of resistance on the part of the ligaments from intraarticular effusion. In the way of prevention, the flexion of the joint should be overcome and the limb be immobilized. After the luxation has taken place, the tendency to recurrence should be obviated after reduction, by massage, electricity, and other measures calculated to restore the tonicity of the wasted muscles.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 3, 1884.

THE PRESIDENT, FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

IMMEDIATELY after the reading of the minutes the polls were opened for the

ANNUAL ELECTION OF OFFICERS.

The result was as follows:

Vice-President.—Dr. Robert F. Weir.

Member of the Board of Trustees.—Dr. C. R. Agnew.

Treasurer of the Board of Trustees.—Dr. F. A. Castle.

Member of the Committee on Admission.—Dr. Daniel Lewis.

Member of the Committee on Ethics.—Dr. C. D. Varley.

Member of the Committee on Education.—Dr. W. G. Wylie.

Member of the Committee on Library.—Dr. A. Jacobi.

THE REPORT OF THE TREASURER.

Dr. W. F. Cushman showed that during the year ending December 15, 1883, the receipts had been $4249.57, and the disbursements $4429.78, leaving a deficit of $179.79, which had been covered by a temporary loan. In the

REPORT OF THE BOARD OF TRUSTEES,

the Academy was congratulated on the character of the papers presented during the year, and the scientific discussions which they had elicited, and on the condition of the society's building and library. There had been, too, a marked increase in the number of readers, and the library and reading-rooms were frequently visited, not only by physicians, but also by lawyers and laymen from all parts of the State. The report was signed by Dr. G. M. Smith, Secretary.

THE REPORT OF THE RECORDING SECRETARY

showed that during the year twenty new Resident Fellows had been elected, while the deaths embraced seven Resident Fellows, one Non-resident Fellow, and one Honorary Fellow. There had been one resignation. The roll of the Academy now consisted of 380 Resident Fellows, 18 Non-resident Fellows, 43 Corresponding Fellows, and 6 Honorary Fellows. Total, 447.

The reports of the Corresponding and Statistical Secretaries, and of the Committees on Admission, Ethics, and Education were read by title, and the

REPORT OF THE LIBRARY COMMITTEE

was read in full. It stated that the number of visitors during the year was 4699, and the number of blanks filled in the circulating department 395. The donations during the year had consisted of 721 bound volumes, and 1839 pamphlets; and 7349 copies of medical journals had been received. The estimates for the ensuing year were as follows:

For salaries, ...	$1212 00
For journals, ...	650 00
For incidental expenses, . . .	138 00
Total, ...	$2000 00

DR. FRANCKE H. BOSWORTH then presented a

PORTRAIT OF THE LATE PROF. JAMES R. WOOD,

on behalf of a number of his old students. In the course of his address, he stated that it was not as the eminent surgeon, nor as the great clinical teacher, that he wished to speak of Dr. Wood to-night, but rather as a beloved and revered preceptor; and he thought that it was in all probability the recollection of his own early struggles that made Dr. Wood so eager to aid his students in every possible way in preparing them for their future work, and making positions for themselves. No one could come in contact with him without feeling his magnetic influence, and it was his wonderful enthusiasm for teaching, he thought, which was the secret of his extraordinary success in this field. The portrait had been painted by the well-known artist, Mr. Thomas Hicks, and its fidelity would speak for itself. No more fitting place could be found for this work than the Academy of Medicine, and it was the desire of those contributing it that it should always remain upon its walls as the memorial of one who was not only a great surgeon, and a great clinical teacher, but, above all, one who was the friend of the medical student.

THE PRESIDENT accepted the gift on behalf of the Academy in some appropriate remarks, and then introduced DR. FREDERICK S. DENNIS, who read a

MEMOIR OF DR. WOOD.

In the beginning of it, he said that Dr. Wood was personally identified with the Academy of Medicine more closely than with any other society. To it he had made his most valuable scientific contributions, and on its platform he had delivered his last public address. Dr. Dennis gave a detailed account of his early years, and spoke of the taste for anatomy which he developed even in his youth. He was accustomed to spend his summers in hunting and fishing on Long Island, and it was a favorite amusement of his to prepare and mount the skeletons of small animals and fish; so that the sports of the boy, he believed, really determined the career of the man.

He then proceeded to speak of him more particularly in the three great departments of his professional labor; as founder, clinical teacher, and surgeon, and said that his work, both for quality and extent, took high position among the best. He showed him to have been a great

politician, but one of the highest character, who never could be induced to accept any office whatever; and gave a history of the means by which he obtained control of the public institutions of the city, from which resulted the establishment of Bellevue Hospital on its present basis, and the foundation of Bellevue Hospital Medical College. One of the earliest objects which he had in view was the formation of the anatomical and pathological collection which has since become so famous, and for the enrichment of which he constantly offered prizes for the best mounted specimens. This museum he presented to the Commissioners of Charities and Correction in 1856, and up to the time of his death it was his aim and ambition to make it as complete as possible in every department. Of it, Dr. Willard Parker had remarked that it was the greatest monument ever erected to any surgeon in this country, and the London *Lancet* had paid the highest tributes to its value.

The attendance at Dr. Wood's surgical clinics at Bellevue Hospital often reached nearly one thousand individuals, and the present system adopted in almost all the medical colleges of combining much more largely than formerly clinical with didactic teaching, owes much to his efforts in this direction. In the treatment of surgical cases the three points on which he laid most stress were rest, cleanliness, and free drainage. Surgical cleanliness was a *sine qua non* on which he always insisted, and which he carried out in the minutest detail in practice. In his operations he never used sponges, but substituted for them pieces of lint which had been dipped in a solution of carbolic acid, and which were thrown away after being used once.

Having spoken of his contributions to surgical literature, Dr. Dennis went on to glance over the long list of his operations, and the many triumphs that he won in almost untried fields. He mentioned particularly his success in periosteal surgery, in operations upon the arteries for aneurisms and other pathological conditions, and in the surgery of the nerves. Up to the year 1879 he had performed nearly one-fourth of all the operations that had been ever done in the world for the relief of tic douloureux by the removal of Meckel's ganglion. His reputation was an international one, and at the German Medical Congress, in 1877, the distinguished Langenbeck had exhibited the celebrated jaw-bone of the Wood Collection, reproduced from the periosteum, with the remark that there was not another such specimen in the whole of Europe. The *Lancet* had also sung his praises as one of the pioneers of periosteal surgery. In genito-urinary and abdominal surgery, in addition, he was a very successful operator, and the last occasion when he spoke in any society was when he made his reply before the Academy of Medicine to Dr. Sims's paper on gunshot injuries of the abdomen. The latter had advocated the opening of the peritoneal cavity as in ovariotomy, but he had opposed this on the ground that in ovariotomy the patient was prepared by preliminary treatment, and there was no shock till after the operation, while in gunshot injuries of the abdomen the patient was already in a state of shock, and the case was very different. He did not perform ovariotomy himself, as he believed it was an operation which should be left to those who had made a special study of the details of the procedure. One of the last operations which he witnessed was one performed at the Woman's Hospital by Dr. Emmet.

As an operator he was exceedingly bold and dexterous, and the rapidity with which he sometimes operated was remarkable. He had once amputated a thigh in nine seconds, and before the discovery of anæsthetics this celerity was often of the greatest practical importance.

Dr. Dennis then spoke of his labors, in connection with Drs. Payne and Parker, in securing the passage of the dissecting bill now in force, which was only accomplished after four years of hard work; and in establishing, with the assistance of Drs. Flint and Smith, the noble training school for nurses at Bellevue Hospital. In conclusion, he quoted a private letter from Professor Gross, in which he said that in Dr. Wood's death the profession had lost one of its most beloved members, and one of its brightest ornaments.

At the conclusion of Dr. Dennis's paper, DR. T. ADDIS EMMET read a

MEMOIR OF DR. J. MARION SIMS.

Having spoken of his early career, and the papers which introduced to the profession his treatment of trismus nascentium, his vaginal speculum, the use of silver wire sutures, and his operation for vesico-vaginal fistula, he gave an interesting account of his first introduction to Dr. Sims, soon after the latter removed to New York, in 1853. In October of that year he received his first patient from Dr. Mott, the case being a very bad one of vesico-vaginal fistula, with the cervix uteri turned into the bladder. Dr. Emmet then gave a somewhat detailed narration of the organization and subsequent history of the Woman's Hospital, of which Dr. Sims was the originator. He had, however, none of the qualities of an organizer, and the work was thus accomplished in great part with the assistance of others. Among those whose aid was most efficient were Dr. Barker, who possessed great influence with the ladies constituting the Board of Managers, the late Dr. Francis, Mrs. T. C. Doremus, and Messrs. Beckman and Benedict.

He spoke of the triumphs which he achieved at the hospital, and told how his enthusiasm and zeal were sometimes repressed by the more cautious consulting physicians and surgeons, Drs. Francis, Mott, and Stevens. He was by nature a surgeon. He was one of the most dexterous operators he had ever seen, and his ingenuity and fertility of resource were wonderful. He was in no sense a plodder, but was all the time striking out in some new path. Dr. Emmet then gave a synopsis of the work that he accomplished, and remarked that up to the present time the human race had not been benefited to the same extent by any surgical instrument as by Sims's speculum. It had opened up an immense field, in which it had hitherto been impossible to accomplish anything whatever. Among the other instruments and procedures which he had devised or adapted, and which were of the highest service to the gynecologist, were the perineal retractor, the uterine probe, the uterine tenaculum, the use of glycerine and of spongetents, the proper tamponing of the vagina, the probang sponge-holder, the block-tin pessary, and the operation upon the anterior wall of the vagina for procidentia and prolapse of the uterus. While sojourning in Europe, he wrote his *Clinical Notes on Uterine Surgery*, which created such a profound impression throughout the civilized world, and yet which, he himself said, was "simply a voice from the Woman's Hospital." Although this

work was open to many criticisms, its appearance had constituted the turning-point in modern gynecology, or, more strictly, in American gynecology, of which he was the father. It was greatly to be regretted that he had not subsequently revised it, and produced a more systematic and accurate work.

Having spoken of his work in connection with the Anglo-American Ambulance Corps in the Franco-Prussian War, of which he was the head, he alluded to the honors which were showered upon him from every part of the world for his achievements in the field of uterine surgery, and concluded with an eloquent tribute to the noble qualities of his devoted wife, who was the daughter of his old preceptor, Dr. Jones, of South Carolina.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, January 3, 1884.

THE PRESIDENT, R. A. CLEEMAN, M.D., IN THE CHAIR.

BATTEY'S OPERATION.

DR. E. E. MONTGOMERY corrected a statement made in the report of the case of ovariotomy narrated by him at the meeting of December 6, 1883. *Silk ligatures*, not catgut, were used to tie the pedicles.

The convalescence of the patient had been very satisfactory. The temperature did not rise above 99° F. In performing this operation no antiseptic was used; all instruments, sponges, etc., were washed in boiling water, and boiled water was used in washing the wound and abdominal cavity. The mental condition of the patient was such that she was kept constantly under mechanical restraint, and on one occasion, when she had been left alone for a few minutes, she tore all the dressings off of the wound, and at the next visit it was found bare, but no bad results followed. The sutures were removed on the eighth day. Some pain in the lower part of the abdomen and slight fever commenced on the twenty-fifth day, but she has since again improved. Her mental condition is at the present better than it had been for a year before the operation, and she can now converse rationally.

SEPTICÆMIA AFTER ABORTION.

DR. W. H. PARISH reported the following case. A young woman, twenty years of age, came into the Philadelphia Hospital in the finishing stages of an abortion which had been coming on for some days. The cause was unknown, but was probably instrumental. At the time I first saw her, three days after her admission, her temperature was 103° to 104° F., and pulse 150. She had had a chill before admission; her abdomen was distended and tender, and the uterus was very sensitive. The right parotid gland was swollen and painful. It continued to enlarge, and, fearing septicæmia, he gave fifty grains of quinine daily, by rectum, as the stomach was too irritable to retain it. One ounce of whiskey was given by the mouth every hour, day and night. A small quantity of morphia was given to relieve the abdominal tenderness. The pulse and temperature fell rapidly, but the gland continued to be swollen and painful; it was quite hard, and discolored. There were no chills now; but fearing the presence of pus, he made an opening by Hilton's method, incising the skin, and using a director to tear through the gland tissue, which was enlarged by passing a pair of forceps, closed, along the groove of the director, and withdrawing them opened. This opening gave exit to two or three fluidrachms of pus. The gland now improved in appearance, but another abscess opened behind the gland and discharged freely. The two abscesses did not communicate. The patient is now convalescent.

The following were then elected

OFFICERS FOR 1884:

President.—Richard A. Cleeman, M.D.
Vice-Presidents.—B. F. Baer, M.D., W. T. Taylor, M.D.
Secretary.—W. H. H. Githens, M.D.
Treasurer.—Alfred Whelen, M.D.
Librarian and Curator.—T. Hewson Bradford, M.D.
Councillors.—R. P. Harris, M.D., Lewis D. Harlow, M.D., Wm. Goodell, M.D., T. M. Drysdale, M.D.
Publication Committee.—John H. Packard, M.D., James V. Ingham, M.D., Elliott Richardson, M.D., B. F. Baer, M.D.

TORONTO MEDICAL SOCIETY.

Stated Meeting, December 6, 1883.

THE PRESIDENT, I. E. GRAHAM, M.D., L.R.C.P. LOND., IN THE CHAIR.

(Specially reported for THE MEDICAL NEWS.)

DR. MACPHEDRAN presented the larynx, and related the case of a child, aged four, that died from

SPASMODIC LARYNGITIS.

He had suffered from frequent attacks of croup from infancy; otherwise perfectly healthy. Two years ago had a severe attack, and the physician in attendance ordered alum as an emetic, and gave a warm bath. The child was very ill for three days. Since then the same treatment had been followed in each attack, and always with satisfactory results.

On the evening of October 15th, he was apparently perfectly well, suffering from no hoarseness or other signs of cold. At 11.30 P.M. was suddenly awakened by severe dyspnœa, with stridulous breathing. Free emesis was produced with alum, and he was put into a warm bath, after which he was rolled in blankets, but without any relief. The dyspnœa gradually increased in severity, and he died at 2.30, about three hours from the commencement of the attack. The doctor did not see him till about fifteen minutes after death.

Autopsy (twelve hours after death).—Lungs much congested with venous blood; heart normal, left side contracted and empty, the right dilated and filled with venous blood. The mucous membrane of the larynx and trachea was somewhat livid, and there was slight thickening above the vocal cords.

This was a case, doubtless, of subacute catarrhal inflammation of the larynx, in which the irritation caused tonic spasm of the glottis. Morell Mackenzie believes that spasm plays only a secondary part in these cases, the chief cause being a collection of inspissated mucus deposited on the vocal cords during sleep, narrowing the chink of the glottis to such an extent as to impede the free ingress and egress of air; then spasm is excited.

DR. HOLMES recommended turpeth mineral as an emetic in these cases.

DR. CAMERON thought that it would be advisable in such cases to resort to tracheotomy and artificial respiration, even if the case were not seen until a few minutes after death. He had used turpeth mineral; in one case it failed to produce vomiting, but purged the child out of the world.

DR. MACPHEDRAN had also had a fatal result with this emetic. (For full report see THE MEDICAL NEWS, Dec. 22, 1883.)

THE PRESIDENT, DR. GRAHAM, reported the following peculiar

CASES OF EPILEPSY,

showing the first case: H. S., æt. 12, female, came under my observation in October, 1883. Patient was in fair health until about two years ago, when the parents noticed the epileptic attacks. It is probable, however, that she had been previously subject to the disease, but that, owing to the occurrence of the paroxysms at night, they had not been noticed. So far as could be judged from the description, the first seizures noticed were those of ordinary epilepsy. She was immediately placed under medical treatment, and was free from the attacks for about five months. They then returned with increased frequency and severity.

About a year ago, they changed in character. It was noticed that she had frequently spasms of the left leg. These spasms presented all the symptoms of localized epilepsy. She would first experience a pain in the popliteal space; then the limb became rigid, which condition was shortly followed by clonic spasms. The patient would retain her consciousness during the seizure. When, however, the spasm of the leg was more than usually severe, it would end in a general epileptic convulsion, with the ordinary symptoms. During the past year, the spasms have been of three types: first, and by far the most frequent, the localized epilepsy of the left leg; secondly, the spasm of the limb, followed by a general convulsion; and a third variety which occurred very rarely—general convulsion without any previous spasm of the leg. The left leg is always more or less rigid, a condition which gives the patient a very peculiar gait. The patella tendon reflex is not exaggerated on that side.

During the time when the patient was presented to the Society, two spasms of the leg occurred. The symptoms were identical with those already described.

In connection with this case, the President related the following remarkable coincidence. For the histories of the cases, he is indebted to Dr. McAlpine, of Janetville, under whose observation the patients came.

Case I.—Patrick G., æt. 66; married, and the father of a family. He has suffered from epilepsy from his youth, but of late years the attacks have been more frequent. They often occur every two or three hours for days together. He came to Dr. McAlpine on a Sunday afternoon with the following history: He went to bed as usual on the previous evening, and during the night he was awakened by a severe pain in the left shoulder. He then found that he had lost the use of his left arm. The Doctor, on examination, discovered a dislocation of the head of the left humerus backwards. Chloroform was administered, and the shoulder easily reduced.

Case II.—During the following night (Sunday), Dr. McAlpine was called to see a brother of the former patient. He was sixty-two years of age, and had also been the subject of epilepsy. He had gone to bed as usual, and was awakened about midnight with severe pain in the left shoulder. He found his left arm stiffened and useless. There was found a dislocation similar to the one in the former case. It was easily reduced without chloroform.

DR. CAMERON exhibited the brain and read the notes of the case of Mrs. G., æt. 40, married twenty-two years ago, several children, one miscarriage in early days of wedded life, children healthy; husband healthy; previous personal history discloses no ill health. Thin, spare woman; not gray or bald; marked capillary ectasia in skin of nose; no other external evidence of disease or degeneration. Eyesight has deteriorated in last two or three years. Never suffered from any ear-trouble; not subject to headaches. Pulse on admission hard, incompressible, high-pressure. Three weeks ago, patient having previously been in her usual supposed good health, was suddenly seized, while engaged in housework, with pain in the right side and back of head and neck. Soon afterwards an epileptiform seizure came on, followed by unconsciousness which persisted for several hours. When consciousness returned, complaint was made of pain in right side of head and back of head and neck and uncontrollable vomiting for forty-eight hours. Dr. R. H. Robinson, who saw her at that time, found deviation of the tongue to the right on protrusion. Patient's condition then somewhat improved, but in ten days another convulsion, accompanied with similar phenomena, occurred. Improvement seemed to follow brisk purgation. Five days later she was admitted to the hospital. She was then cyanosed and unconscious. Pupils contracted, equal, responding to the stimulus of light. Slight passive divergence of eyeballs. Respiration quick and shallow, no puffing of cheeks or lips on expiration. Pulse hard, incompressible, over 100. Muscular tonicity of right side normal; *partial* left brachial monoplegia. Skin reflexes slightly diminished; tendon reflexes also slightly diminished, certainly not exaggerated. Potassium bromide, aloes, and asafœtida administered; could swallow solid bolus better than liquids.

Next day consciousness returned; bowels had acted; passed urine, asked for utensil; could answer questions rationally. Complained of pain in right side of head and back of head and neck, and also back; could move all four limbs; grasp of left hand weaker than right; legs manifested an irresistible tendency to fall out of left side of bed; had to be pinned in. Urine laden with urates, no albumen; tongue protruded straight.

Next day, felt somewhat better; pain in head and neck persists. Ophthalmoscopic examination—kindly made by Dr. Reeve—entirely negative.

Next day still felt somewhat better; head rotated markedly to the right, any attempt to straighten it is painful. Other symptoms not changed. No marked localized tenderness in scalp. No valvular cardiac lesion. Temperature 101° Fahr. Aneurism thought to be excluded; tumor likewise; syphilitic gummata likewise; embolism probably; hemorrhage not likely, from age and sight of lesion; thrombosis of right lateral sinus, with effusion and pachymeningitis leaned to, but diagnosis not made.

Next day no change; quite rational.

Next day, coma, cyanosis, rapid breathing and pulse; death.

Post-mortem Examination (six or eight hours after death).—Brain: thin layer of blood beneath pia mater and dipping into sulci on right side, and extravasation columnar in shape, half an inch in diameter, extending through the brain substance from half an inch from cortex to the base, being two inches posterior to Sylvian fissure at base, and half an inch at upper surface. Heart, concentrically hypertrophied; no valvular lesions. Lungs somewhat emphysematous; liver healthy; kidneys small capsule adherent, cortex granular.

MR. A. H. WRIGHT presented the following notes of a case of

NEPHROTOMY FOR PYELITIS,

and exhibited the kidneys.

J. P., male, æt. 37, a shoemaker, born in Ireland, admitted to the Hospital April 27, 1883. Nothing special in family or previous history. Thinks he never had gonorrhœa, although he had two sores on penis twenty years ago. Since last September he has had "trouble with his bladder," frequency of micturition, and pain felt near end of penis. At first the pain was worse before micturition, but lately, worse at close of the act. Noticed three small blood-clots in March in chamber after voiding urine. For a short time in March and April a little blood followed urine occasionally. The pain is now very severe; felt near end of penis, especially at close of micturition. Passes water four or five times an hour during the day, and nearly as frequently at night. Unable to work during last two months. Ordered benzoic acid, biborate of sodium, and infusion of buchu.

May 3.—Stricture found in bulbo-membranous portion of urethra, admitting only No. 1 English catheter. Prostate tender per rectum, and slightly swollen. Less pain and frequency of micturition. Blisters applied to perineum. Examination of urine showed abundance of pus cells, a little albumen, specific gravity 1012, acid reaction, no casts. Endeavored after this to dilate stricture by simple dilatation, but failed. Then tried continued dilatation, commencing with a No. 1 English, which was retained three days, after which a No. 2 was used. In twelve days the stricture would only allow the passage of No. 5. Could not find calculus in bladder.

During latter part of May appeared better; had less frequency of micturition; but in June was worse again, and had occasional increase of temperature.

June 19.—Passed a Holt's dilator, intending to "rupture" stricture, but as a severe rigor ensued, it was at once withdrawn.

July 12.—Performed external urethrotomy with a guide, and allowed urine to flow through perineal opening. The stricture was cut through without difficulty. The bladder was explored easily, but was found to contain no calculus. There was abnormal condition of prostate. Bladder apparently slightly contracted. Pain much relieved by operation, and was able to retain urine about two hours; was in good spirits, as he thought his condition vastly improved.

In August it was found that pus still passed; sometimes by the perineal opening, sometimes mixed with urine, and occasionally alone, either at commencement or end of micturition. Sometimes urine appeared quite clear for a day, or a day and a half, and then a quantity of pus would pass, either alone or with the urine. At one time, after an interval of nearly two days, about an ounce of pus passed alone. Careful questioning at this time elicited the fact that there was occasional dull pain in right loin, not descending towards groin, apparently worse before the passage of pus. A careful examination on various occasions showed no certain signs of swelling in this region.

Urine examined frequently without discovering anything new; reaction always acid; some albumen, probably no more than presence of pus would account for; no casts. During this month (August) the perineal wound closed up for a few days, but again opened, and remained so during life; some urine passing through fistula and some through urethra. Occasionally had chills and increased temperature, and attacks of diarrhœa, which were generally easily controlled.

In September he seemed somewhat better, and passed less pus. Worse again at end of month. Had chills, loss of appetite, and irregular—sometimes high—temperature. Slight signs of swelling in right loin suspected.

October 15.—Percussion showed dulness limited to a space not greater than a finger-breadth, midway between last rib and crest of ilium. There appeared to be a slight swelling when two sides were carefully compared. No fluctuation could be made out.

18th.—The large needle of aspirator was introduced between last rib and ilium, six inches from spine. It passed easily into a good-sized cavity, from which seven ounces of pus escaped. Examination of urine showed no special change.

Felt rather better after use of aspirator, but in four or five days diarrhœa returned. Evacuations slightly dysenteric in character.

28th.—Nephrotomy performed with antiseptic precautions, including the spray. Patient under ether, which he took badly. Ordinary lumbar incision, commencing at last rib, three inches from spinous processes, passing downwards and slightly outwards to crest of ilium; passed through portions of latissimus dorsi, and then cut through lumbar fascia and transversalis fascia on a director; then passed finger past outer edge of quadratus lumborum. The tissue behind kidney (principally fat) was scraped away, mostly with finger, when sac came in view. This was seized with a volsellum forceps and opened freely. About six or seven ounces of pus escaped; the edges of sac were then fastened to integument on each side of superficial incision. There was very little bleeding. No vessels tied.

Patient rallied fairly well, and seemed pretty comfortable during evening. Stomach was irritable, and there was some vomiting during night. On following morning condition about same—unable to take much nourishment. At 11 A.M. commenced to sink, and remained very low notwithstanding injection of ether, hypodermically, and nutrient enemata. Died on following day, two days after operation.

Post-mortem Examination (five hours after death).—Body emaciated. Right kidney, capsule thickened and adherent to surrounding tissue; numerous adhesions, especially to ascending colon; kidney tissue partially destroyed. No pelvis could be made out. Ureters much thickened and lumen very small. Left kidney weighed ten ounces.

When this patient was first admitted, he was treated for cystitis and stricture. The stricture was very obstinate, and prevented exploration of bladder. The perineal blisters were expected to relieve the prostatitis, if any existed. The perineal section was performed for three purposes: 1st. To cure the stricture; 2d. To relieve the cystitis; 3d. To explore the bladder. It was very satisfactory for all three purposes, the only drawback being the continuance of the fistula. It was found quite easy to explore the whole of the interior of the bladder. The exploration showed the bladder to be comparatively healthy. It was not until after this that pyonephrosis was suspected, but it was extremely difficult to discover any physical signs of such in the loin. This may be partly understood by an examination of the sac, which was composed of the capsule and a very small portion of kidney substance. The sides of the pelvis were to a large extent agglutinated. The sac and its contents occupied the normal position of the kidney, and filled but little if any more space than the left kidney, which weighed ten ounces. Generally, in such cases, the pelvis and ureters are largely dilated, and form part of the sac. Under these conditions the swelling often extends beyond the median line, and can be easily detected.

As the other kidney was fairly healthy, and had evidently secreted all the urine for some time, and as the other organs were in pretty good condition, it is quite likely that earlier operative interference would have prolonged the patient's life considerably. It seems likely that the stricture was the origin of the trouble, causing first cystitis, after which the inflammation extended up the right ureter to the pelvis and substance of kidney.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 15, 1883.

THE PRESIDENT, WM. M. WELCH, M.D., IN THE CHAIR.

DR. ARTHUR V. MEIGS presented

PROOF THAT HUMAN MILK CONTAINS ONLY ABOUT ONE PER CENT. OF CASEIN; WITH REMARKS UPON INFANT FEEDING.

Nearly two years ago, in a paper upon "Milk Analysis," Dr. Meigs described the method he had worked out, and briefly detailed his results. The main conclusion was that human milk never contains more than about one per cent. of casein, and this observation he then claimed to be a new one, and very important, as showing how we should feed infants so unfortunate as to be deprived of their natural sustenance. A year ago or more, he delivered a lecture to the class at the Pennsylvania Hospital, which was subsequently published in THE MEDICAL NEWS of November 4, 1882, in which he described a plan of feeding deduced from the results of numerous experiments and analyses. He now offered proof that the results arrived at by the method of analysis are correct, and he then proceeded to make some suggestions about the proper method of infant feeding.

In the endeavor to find a food which shall be the best for infants who have to be hand-fed, he said, there are two considerations, either of which might be selected as the basis from which to start. In the first place, the desired goal might be attained by making trial of all sorts of foods, and these being put to the test of experience, the good would be retained and the bad gradually weeded out, until at last perhaps the most suitable would be found, and slowly introduced. On the other hand, the desired end might be attained by trying to produce a food which should be, as nearly as possible, like what nature has provided for the infant. Many trials have been made in the past by both these methods, but to the second one justice has never been done; for, if his conclusions are correct, a proper understanding of the composition of human milk, from which to start, has been wanting.

The artificial food which Dr. Meigs recommends is, upon theoretical grounds, what a food for infants should be; for in the artificial food the elements have been introduced in the same proportions as they exist in human milk. For a long time the great majority of writers upon infant diseases and diet have recommended that cows' milk should be diluted before giving it to young infants; and this, they all agree, is because it contains too much casein, which causes a curd that only infants of the strongest digestion can with safety assimilate.

The necessary data being now at hand, it is comparatively easy to construct a food which shall, at least, be more nearly what is needed than any previous one. In making such a food there are two matters to be considered: the proximate constituents must be in the same relative proportions as they are found in human milk, and they must be in a medium which shall be, as human milk is, alkaline. This latter end is easily accomplished by the use of a due amount of lime-water, and is justified by the fact that it is a matter of experience, almost universally acknowledged as true, that it is a most useful adjunct, rendering cows' milk more easy of digestion by the human stomach. The quantity of lime-water to be used should be one-fourth of the total by measure. This may seem to many persons an excessive quantity, but when it is understood that if made as ordinarily directed, by agitating water with lime and then filtering, it contains only two decigrammes of lime in each litre, it becomes plain that the use of lime-water means the administration of a great deal of water and very little solid matter.

The experiments show that the addition of lime-water alters the coagulability of the casein when experimented with, whatever may take place in the stomach. Whatever may be the value of these artificial experiments, the great reason for the use of lime-water is that experience has found it good.

So far as bringing the other proximate constituents to like proportions with those in human milk, the first step must be so to dilute with water as to get the desired quantity of casein; the fat and sugar can be increased by the use of the necessary quantities of cream and commercial milk-sugar. Taking the averages of cream and good city milk, it will be found by calculation that if there be mixed together ten cubic centimetres of cream, five cubic centimetres of milk, ten cubic centimetres of lime-water, and fifteen cubic centimetres of water, with two and two-tenths grammes of milk-sugar, the desired mixture is had.

The easiest way to prepare and use the food is as follows: there must be obtained from a reliable druggist packages of pure milk-sugar containing seventeen and

three-quarters drachms each. The contents of one package are to be dissolved in a pint of hot water, and it is best to have a bottle which will contain just one pint, as there is then no need for further measuring. The contents of one of the sugar packages are put into the bottle, and when filled with hot water the sugar soon dissolves, and it is ready for use. The dry sugar keeps indefinitely, but after it is once dissolved it sours if kept more than a day or two in warm weather; it is understood, therefore, that the sugar-water must be kept in a cool place, and if it should at any time become sour, as is easily discovered if it is smelled and tasted, it should be thrown out, and after the bottle has been carefully washed with boiling water, the contents of a fresh package dissolved. A milkman must be found who will serve every day fresh, good milk and cream. By good milk is meant ordinary milk, such as is easily procured in most cities, and not rich Jersey milk; and in the same way the cream should be such as is ordinarily used in tea and coffee, and not the very rich cream of fancy cattle. The reason that ordinary milk and cream are recommended, is because they are within the reach of almost every one. When the child is to be fed, the nurse should mix together two tablespoonfuls of cream, one of milk, two of lime-water, and three of the sugar-water, and then as soon as the mixture has been warmed it may be poured into the bottle and the food is ready for use. If the infant is healthy, this quantity will not satisfy it after the first few weeks, and then double the quantity must be prepared for each feeding.. Twice as many tablespoonfuls of each of the ingredients must be mixed together, making sixteen tablespoonfuls (about half a pint) in all.

This food should not be given any stronger until the child is eight or nine months old at least; but if the infant is a healthy one, it may take as much of it as it wants, but always of the same strength. A robust infant will often take three pints, or even more, in each twenty-four hours. It is an easy matter for any one to learn how to make the lime-water; and it is advisable to have it made at home, for a great deal is used, and if it is made at home much trouble and expense are saved.

With regard to the propriety of increasing, from week to week, the strength of any artificial food given to infants, there has been some question. Most authorities have advised that the foods should be increased in concentration until finally the infant is given pure cow's milk. The propriety of this procedure, during the earlier months of life at any rate, is very doubtful. Although there is some reason to believe that the quantity of solid ingredients in human milk increases from month to month as lactation goes on, such an opinion should be accepted only with great caution, for it seems likely that if there is any increase in the concentration of the milk after the colostrum has once disappeared, and the nursing process has settled down into its even course, the increase is so slight that it may be disregarded. Analyses show that the milk of a woman whose child is two months old does not differ materially from that of one whose child is twelve or fifteen months old. If, then, nature has made no difference, which our means of analysis will detect, between the milk of a woman who has been nursing two months, and one who has nursed twelve, an artificial food which has been found to suit an infant of two months, should be made more concentrated only very gradually, and with careful observation of the effect upon the health of the infant. It is best, therefore, if the infant thrives and grows as it should, not to make any change in the food until after six to nine months of age have been attained.

BALTIMORE.

(From our Special Correspondent.

THE NEW BIOLOGICAL LABORATORY OF THE JOHNS HOPKINS UNIVERSITY was formally opened on the evening of Wednesday, January 2d. Prof. H. N. Martin delivered an address on "Modern Physiological Laboratories: What they are and Why they are." After the address, the audience inspected the building.

PARIS.

(From our Special Correspondent.)

WIRING THE FRACTURED PATELLA.—THE MEDICAL NEWS of December 1, 1883, contains an editorial on the treatment of fractures of the patella by suture of the fragments. La Société de Chirurgie de Paris has recently had this question up for discussion, and a brief *résumé* of the opinions expressed by the surgeons of the French capital on this subject will be of interest.

Some months ago, M. Beauregard, of Havre, presented to the Society a case upon which he had performed osseous suture of a fracture of the patella, one day after the receipt of the injury. Success was not complete, and M. CHAUVAL, who was requested to make a report on the case, did not express himself as entirely in favor of the operation. M. Chauval has collected forty-three analogous cases, of which three died, and amputation had to be resorted to in one. In thirty-three cases, the results were good in twenty-eight, bad in five. Atrophy and weakness of the limb, after the operation, are the rule; fibrous union is more usual, osseous union being the exception. M. Chauval thinks that in case of old fracture of the patella, with functional weakness of the limb, osseous suture is a useful operation, and should be resorted to; in recent fractures it should be solely reserved for those cases in which coaptation of the fragments is absolutely impossible by any other means. He states that one is not likely to die from a fracture of the patella, while an arthrotomy may be fatal, which should render the surgeon cautious. If, however, the operation is performed, every antiseptic precaution should be rigorously observed, and the limb should be placed in an immovable apparatus, and retained there for a month.

M. LUCAS-CHAMPIONNIÈRE referred to Lister's seven cases, and thought that immediate osseous suture in fracture of the patella was a good operation when performed with antiseptic precautions. He said that the statistics of M. Chauval were made up of dissimilar cases, taken from several surgeons, and that Mr. Lister's results should not be compared with those of inexperienced surgeons, who have failed where the surgeon of London has succeeded.

M. L. G. RICHELOT said that the main object to be

sought for in treating fractures of the patella, was to assure a useful limb; but loss of function does not depend on the separation of the fragments alone, but also on atrophy of the rectus femoris, which frequently occurs in fracture of the patella. There are patients who have recovered from the fracture itself, there being no separation of the fragments, but who cannot walk because of an atrophied biceps femoris. Others, again, walk well, in spite of a separation of six, eight, or ten centimetres or more, because this muscle is not atrophied. In the former it is not suture of the separated fragments that is needed, but electrization of the biceps. Admitting, then, that antiseptic arthrotomy is a good operation, it is necessary, before performing it, to be assured that it is really demanded, and only after having ascertained that the biceps is not atrophied; for union of the fragments will be of no avail if the muscle inserted into the upper fragment is powerless.

M. GILETTE had had two cases of suture of the fragments, one being a compound fracture, the other an old fracture with troubles of locomotion, which none of the ordinary means could relieve. He entirely adopted the views of M. Richelot as to the value of functional activity of the biceps.

M. VERNEUIL absolutely rejected the operation of suture of the fragments; he considered it as more dangerous than the affection for which it was performed. Where there is no wound, two plates of plaster of Paris, held together by a caoutchouc tube, suffice to hold the fragments in position, the limb being placed in a gutter; when the fracture is compound, the same apparatus, held by a band around the whole limb, and the gutter are sufficient for treatment. He agrees with M. Richelot, that functional impotence of the limb is due especially to paralysis of the biceps. Several cases of this nature have been reported by M. L. H. Petit, and there can be no doubt as to the facts. (The cases alluded to by M. Verneuil were published in *L'Union Médicale*, Nov. 29 and Dec. 1, 1883, Nos. 169 and 170.)

MM. FORGET and LABBÉ fully agreed with M. Verneuil. MM. LE FORT and DEPRÈS protested, with M. Verneuil, against antiseptic arthrotomy and osseous suture in these cases.

M. TRÉLAT thought that the operation should never be performed in recent operations; that an indication for it might exist in certain rebellious cases which resisted all treatment, but that he had not yet encountered any. However, he did not absolutely reject the operation in old cases.

M. LARGER presented a patient who had sustained fracture of the patella four times, twice on each side. The separation amounted to one and one-sixth inches on the right side, and to more than four and two-thirds inches on the left; nevertheless the patient walked very well, as the muscles are sound, which confirms the views of MM. Verneuil and Richelot. In certain cases, as reported by M. Richelot, the movements of the limb are preserved in spite of atrophy of the biceps and separation of the fragments, when the ligaments uniting the two vasti to the lower fragment are not ruptured. M. Picqué has published cases confirmatory of this opinion in *L'Union Médicale*, Dec. 4, 1883, No. 171. M. Henriot has also published in the same journal, Dec. 9, No. 174, another and more curious case. The patient had a fracture of the patella, without separation of the fragments, and he could not walk because the biceps was atrophied. Electricity restored the muscle, which then caused an elongation of the callus, as yet but little solid, and a separation of the fragments of about three and one-sixth inches. Nevertheless the solidity of the limb was much greater than before the separation, on account of muscular atrophy, and the patient walked better than before the separation.

M. Pozzi has very recently presented to the Société de Chirurgie, an insane patient upon whom he has practised suture of the fragments with success. M. Pozzi is a partisan, generally, of suture in recent fractures, but in this case he did it through necessity, on account of the restlessness of the patient.

The Société de Chirurgie is not, then, favorable to suture of the fragments in the treatment of old or recent fractures of the patella.

COLLEGE OF PHYSICIANS OF PHILADELPHIA—ANNUAL MEETING AND ELECTION OF OFFICERS.—The annual meeting of the College of Physicians was held January 2, the President, Dr. Alfred Stillé, in the Chair. The President read his annual address, which was a review of the work of the past year and an historical retrospect of the life of the college.

The result of the balloting for officers and standing committees for the year 1884 was as follows:

President.—Dr. Samuel Lewis.

Vice-President.—Dr. J. M. DaCosta.

Secretary.—Dr. Richard A. Cleeman.

Treasurer.—Dr. Charles Stewart Wursts.

Honorary Librarian.—Dr. J. H. Hutchinson.

Recorder.—Dr. J. Ewing Mears.

Censors.—Drs. Lewis Rodman, Edward Hartshorne, Wm. Goodell, and Alfred Stillé.

Councillors.—(To serve until January, 1887.) Drs. S. W. Gross and James C. Wilson.

Committee on Publication.—Drs. James H. Hutchinson, Robert P. Harris, and A. V. Meigs.

Library Committee.—Drs. S. Lewis, Walter F. Atlee, I. Minis Hays, S. W. Gross, and Morris Longstreth.

Committee on Mütter Museum.—Drs. Wm. Hunt, S. Weir Mitchell, and John H. Brinton.

Hall Committee.—Drs. Edward Hartshorne, Lewis Rodman, T. H. Bache, W. S. Forbes, and H. Y. Evans.

Committee on Lectures.—Drs. Samuel D. Gross, Joseph Leidy, William Goodell, William F. Norris, and John H. Packard.

Committee on the Directory for Nurses.—Drs. W. W. Keene, A. H. Smith, and Wharton Sinkler.

PHILADELPHIA COUNTY MEDICAL SOCIETY'S ANNUAL MEETING.—The annual meeting of the Philadelphia County Medical Society was held on January 2d in the Hall of the College of Physicians—the President, Dr. William M. Welch, in the chair. Reports of the Standing Committees and of officers were received and filed. The following officers were then elected to serve during the ensuing year:

President.—Dr. Wm. M. Welch.

Vice-Presidents.—Drs. Wm. S. Forbes and S. R. Knight.

Recording and Reporting Secretary.—Dr. Henry Leffmann.

Corresponding Secretary.—Dr. M. S. French.
Treasurer.—Dr. L. K. Baldwin.
Censor.—Dr. H. St. Clair Ash.

Two female physicians were applicants for membership, but were defeated, receiving only one-third of the total vote cast.

THE BOSTON DIRECTORY FOR NURSES.—It is stated that the net profits of this institution for the last year were $1200. This handsome sum is devoted to the use of the library of the Boston Medical Library Association.

CONDITIONAL BEQUEST TO HARVARD UNIVERSITY.—The will of the late Dr. Calvin Ellis contains a conditional bequest of $50,000 to Harvard College for the establishment of scholarships. If certain legatees mentioned in the will die without issue, the bequest is to take effect.

ARMY MEDICAL MUSEUM.—DR. JOHN S. BILLINGS has been placed in charge of the Army Medical Museum. This position will not interfere with his duties in connection with the Library of the Surgeon-General's office.

WOMEN STUDENTS AT THE PHILADELPHIA HOSPITAL.—There are about fifteen students at the Woman's Medical College in Philadelphia, fitting themselves as medical missionaries in Asia and elsewhere. Three of them, we understand, attended last Saturday's medical clinic at Blockley—the only women among about one hundred and fifty young men. The lecturer was late, and the class, in their impatience and enforced idleness, began some noisy demonstration, directed, evidently, to the delinquent teacher, but later apparently intended for the women present, not so much in the way of serious insult as of playful banter. Miss A. M. Fielde, one of their number—one of the most widely known and eminent missionaries in China—arose on the inspiration of the moment and amidst instant and most respectful silence, spoke as follows: "Gentlemen: I have been for eighteen years a missionary in China. The Chinese have no medical science, and superstitious rites are chiefly relied on in the treatment of disease. *All* the people are in need of medical aid, but the *women* are the *neediest*. A Chinese woman would under no circumstances go to a male physician for the treatment of any disease peculiar to her sex. She would be prevented by her own womanly delicacy and by all the notions of modesty held by those around her. She would suffer lifelong agony rather than violate her sense of propriety. Her father, her brothers, and her husband would even let her die rather than allow her to be treated by a male physician. Full of sorrow for the sufferings of these women, I have been looking in Christian America to see what hope of help for them might be here. I have been glad to find that in some of our great medical schools earnest and self-sacrificing women are fitting themselves for a work of mercy in Asia and other lands. Unless such women learn to do such work well there is no physical salvation for those afflicted ones. And in behalf of those women, who have no medical care while they so sorely need it, I ask from you the courtesy of gentlemen toward ladies who are studying medicine in Philadelphia." The whole class responded to her earnest address with a cheer, and one of their number, rising, assured the ladies that they had no intention to annoy them. Evidently a new aspect of the case had been presented to many of them, and one which claimed their respect and sympathy.

DR. WILLARD PARKER, of New York, whose condition has been unchanged for several weeks, at last accounts was resting more easily. His great age and the long siege of sickness through which he has passed render his recovery improbable. He may linger an indefinite time; and his death may be expected at any moment.

THE BELLEVUE HOSPITAL TRAINING SCHOOL FOR NURSES.—The Society of the Training School for Nurses attached to Bellevue Hospital held its eleventh annual commencement last Tuesday evening, and twenty-seven young women received diplomas, after which an address was made by Dr. T. Gaillard Thomas. The annual report stated that the school was opened in 1873 by thirteen women, to whom was intrusted the nursing of four wards in Bellevue Hospital. It now numbers sixty-four pupils, and has charge of 258 beds in fourteen medical and surgical wards, the Sturgis and Marquand Pavilions, and the Emergency Hospital attached to Bellevue. The school also nursed 125 private cases last year. Since its opening 105 nurses have been graduated, of whom 25 are engaged in hospital work and 137 in private nursing. There were 813 calls for private nurses last year, of which 184 had to be declined, all the nurses being engaged at the time of application. Over 300 applications for entrance to the school were received, but only forty of the applicants were accepted.

EPIDEMIC OF MEASLES IN BALTIMORE AND WASHINGTON.—An epidemic of measles at Baltimore, Md., has been officially reported to the Surgeon-General, U. S. Marine-Hospital Service. The Health Officer at Washington, D. C., also reports an epidemic of this disease in that city, and gives the total cases, up to December 31, as having been at least five thousand. Scarlet fever is also becoming quite prevalent in both cities.

YELLOW FEVER IN MEXICO.—The United States Consul at Guayamas, in a letter to the Secretary of State, dated December 12, 1883, says: "The so-called yellow fever has almost disappeared from the State; no cases now in the port, and the port authorities grant clean bills of health to vessels departing.

"In the capital of the State, Hermosillo, a few cases of a mild type are said to exist. During the past month but fourteen deaths from all diseases occurred at this port, seven of which are said to have been from the so-called yellow fever—among them were M. F. Chapin, of Maine; O. N. Funk, of Michigan, and an Englishman named F. Jolly.

"It is to be hoped that this fatal fever will never return to this coast; its ravages during the months of August, September, and October will long be remembered by the people of Sonora."

Assistant Surgeon Main, of the Marine-Hospital Service, reports, under date of December 23, that there are still scattered cases of yellow fever at Manzanillo. Mor-

tality ninety-two per cent. Quarantine has been raised on the Guadalajara road, but continues in force against vessels from the south. The "Captain of the Port" is reported as having been removed for not enforcing quarantine restrictions with sufficient vigor—his office includes that of a justice of the peace. At Acapulco the yellow fever still continues in a mild form, and has not at any time been so malignant as at other points in Mexico.

YELLOW FEVER AT HAVANA.—The yellow fever deaths at Havana for the three weeks ending December 29, 1883, are reported by Inspector Burgess to have been twenty-seven.

THE CHOLERA IN EGYPT.—The National Board of Health has information of the continuance of the cholera in Alexandria from Judge Farman, an eminent Judge of the International Tribunal of Egypt, Cairo, who says: "There are from one to three cases a day resulting in death, and many more in which the attacked recover." According to the previous history of the disease in Egypt, it will probably continue all winter, and perhaps much longer. He estimates the number of deaths from cholera during the past summer at double that given in the official reports. The United States Consul-General at Cairo reports the official estimate to be 48,000 to 50,000. After the cholera epidemic of 1865 there were isolated cases for two years. The general state of health, aside from cholera, has been bad at Alexandria. Fever in various forms has been, and still is, quite prevalent.

CONSULAR HEALTH NOTES.—The U. S. Consul at Rio reports to the State Department, that "after a lapse of twenty-four days the yellow fever has again commenced, and that the weather is very hot and dry at Rio de Janeiro."

The U. S. Consul at Buenos Ayres also reports the reappearance of yellow fever in that city.

The U. S. Consul at Calcutta states that the cholera is decreasing in India, only forty-four deaths having occurred from that disease at Calcutta during the two weeks ending November 10, 1883.

THE HUTCHINSON TESTIMONIAL.—On Thursday evening, November 29th, MR. JOHNATHAN HUTCHINSON was the guest of the past and present students of the London Hospital. About one hundred and fifty gentlemen sat down to dinner under the presidency of Sir Andrew Clark, Bart., and, during the course of the evening, Mr. Hutchinson was presented with the testimonial subscribed for by a large number of his old pupils and friends. Sir Andrew Clark, in making the presentation, delivered an eloquent and most effective address; he recalled the memories of the earlier days, when Mr. Hutchinson was an earnest, thoughtful, fervent student in the wards of the hospital which owed not a little of its renown to the world-wide fame of the surgeon who has just ceased active association with its work. Mr. Hutchinson, in reply, briefly sketched the history of his own life, and traced the development of his own mind. He insisted on the intellectual training to be obtained from a constant study of the poets of our native land, and attributed a great part of his life's successful work to the early education he received as an apprentice to a conscientious practitioner, and as a pupil in the small medical school of York, where he alone constituted the whole class in many subjects, and so enjoyed the undivided attention of his teachers.—*Brit. Med. Journ.*, December 8, 1883.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending December 29, 1883, indicate that pneumonia has greatly increased, that inflammation of the kidney, whooping-cough, diarrhœa, intermittent fever, and influenza have increased, and that rheumatism, consumption, and remittent fever have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending December 29, and since, at ten places, scarlet fever at seventeen places, and measles at seven places.

OBITUARY RECORD.—Died suddenly of angina pectoris, on January 5, at the office of Dr. H. I. Bowditch, Boston, Massachusetts, THOMAS W. PERRY, M.D., of Providence, Rhode Island, aged sixty years.

Dr. Perry was born in Hopkington, Rhode Island, and began the study of medicine with his father, a physician of repute, and afterwards studied with Dr. Bowen, of Thompson, Connecticut. Graduating from the New York University Medical School, he practised first in Putnam, Connecticut, and while there married a daughter of Lemuel H. Grosvenor, of Pomfret, Connecticut. Subsequently he removed to Central Falls, Rhode Island, and thence to Providence, where, for many years, he was in partnership with the late Dr. George Capron. During the war of the Rebellion, he was, for nine months, surgeon of the Eleventh Rhode Island Regiment.

Dr. Perry was a successful practitioner and a man of genial and kindly instincts. He had had symptoms of his fatal disease for some time, and went to Boston for the purpose of consulting Dr. Bowditch, after entering whose office he immediately expired.

——DR. JOHN A. ROGERS, of Paterson, New Jersey, died in that city on December 30th, of typhoid pneumonia, at the age of thirty-one years.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 31, 1883, TO JANUARY 7, 1884.

APPEL, DANIEL M., *Captain and Assistant Surgeon.*—Having relinquished the unexpired portion of leave of absence granted by S. O. 68, Headquarters Division of the Atlantic, November 16, 1883, and reported for assignment, assigned to duty at Fort Porter, N. Y.—*Par. 2, S. O. 247, Department of the East, December* 29, 1883.

HARVARD, VALERY, *Captain and Assistant Surgeon.*—Assigned to duty in charge of office of Medical Director, Department of Texas, during the temporary absence of that officer.—*Par. 2, S. O. 164, Department of Texas, December* 31, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to the Editor, Wal[illegible] Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIV. SATURDAY, JANUARY 19, 1884. NO. 3.

ORIGINAL LECTURES.

A COURSE OF LECTURES ON DERMATOLOGY.

Delivered at the University of Pennsylvania during the Session of 1883-1884.

BY LOUIS A. DUHRING, M.D.,

PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY.

(Reported by Henry Wile, M.D.)

LECTURE I.

ANOMALIES OF SECRETION, HYPERÆMIAS, INFLAMMATIONS.

SCIENCE is classified knowledge, and the development of any science is conditioned by improved methods of classification. In dermatology the subject of classification is important from a scientific and from a practical standpoint, and the history of this science shows that various methods of classification, from the most simple to the most complicated, have been proposed from time to time. Two of them may be alluded to. About the beginning of this century Willan grouped the affections of the skin according to the elementary lesions, as, for example, macules, vesicles, papules, pustules, etc. The classification was useful at the time, and was attractive and simple. It was, however, insufficiently comprehensive, embracing by no means all diseases, and if followed out led to confusion.

The classifications in vogue to-day have as a basis that put forth by Hebra and Rokitansky, about forty years ago, and are based upon the anatomy of the skin, the pathology of the lesions, and, to a slight extent, upon their etiology. The following classification, which will be here used, embraces nine classes.

I. Anomalies of secretion (sebaceous glands, sweat-glands); *e.g.*, seborrhœa, hyperidrosis.
II. Hyperæmias; *e.g.*, simple erythema.
III. Inflammations; *e.g.*, eczema, psoriasis, acne.
IV. Hemorrhages; *e.g.*, purpura.
V. Hypertrophies; *e.g.*, chloasma, ichthyosis.
VI. Atrophies; *e.g.*, vitiligo.
VII. New growths; *e.g.*, cancer, lupus, syphilis.
VIII. Neuroses; *e.g.*, pruritus.
IX. Parasites; vegetable, *e.g.*, tineæ; animal, *e.g.*, scabies.

CLASS I.—ANOMALIES OF SECRETION.

SEBORRHŒA may be defined to be a disease of the sebaceous glands, characterized by an excessive and abnormal secretion of sebaceous matter, forming upon the skin an oily coating, crusts, or scales. Two varieties are recognized, namely, seborrhœa oleosa and seborrhœa sicca, which may exist separately or together. Seborrhœa oleosa occurs chiefly on the face, especially the nose and forehead. In its milder form it is not an uncommon affection.

Seborrhœa sicca, or dry seborrhœa, occurs upon the chest and back, but most frequently upon the scalp, where in its milder form it gives rise to what is ordinarily known as dandruff. It consists in the formation of scales, loose or adherent, and when the process continues on the scalp the hairs become dry, fall out, and baldness ensues. Many cases of premature baldness arise from neglected seborrhœa. The same form may attack the hairy portions of the face. On the back and chest the lesions consist of dime or quarter-dollar sized, rounded or circinate spots, covered with dry or greasy scales, with a patulous condition of the ducts of the sebaceous glands. The genital region also may be affected.

Seborrhœa sicca occurs most frequently in light-haired, pale, anæmic subjects, while seborrhœa oleosa is found more in dark-haired subjects. Both forms are met with mostly in adolescence, and they are usually associated with general debility. The secretion seems to be largely under the control of the nervous system, and the pathology of the process is that of a functional derangement of the sebaceous glands with a tendency to subsequent atrophy of the glands and the skin. A microscopic examination of the secretion shows degenerated granular epithelial cells mixed with amorphous, oily, molecular débris.

When existing on the scalp the disease must be differentiated from eczema, psoriasis, and ringworm. Want of infiltration of the deeper layers of the skin, dryness, and excessive scaling are sufficient to distinguish it from the first; its diffusion over large areas, want of sharp definition at the borders, grayish or yellowish scales, on a pale or slightly hyperæmic base, would dispel all doubts as to the second, while a microscopic examination of some of the scales would render it impossible to confound it with the third. On the chest it may furthermore be mistaken for ringworm, but here the microscope would again decide. Then again on the face it may be confounded with lupus erythematosus, but in pronounced cases of the latter there is usually sharp definition of the lesions accompanied by marked infiltration and thickening, also later, by the formation of atrophic scar-tissue, all of which is absent in seborrhœa.

The treatment of seborrhœa is important; it is sometimes an easy matter, at others one of great difficulty. A general constitutional treatment is often useful, the same consisting of out-door exercise, hygiene, regulation of diet, and the administration of cod-liver oil, iron, and arsenic. The latter may be given in the following eligible form:

℞.—Liq. potassii arsenitis, . . . fʒj.
Vini ferri, ... fʒiv.
S.—One teaspoonful three times a day, to be taken in a wineglassful of water after meals.

The sulphide of calcium in doses of one-tenth to one-half grain, kept up for weeks or months, may also be mentioned, the same exerting a tonic effect upon the

sebaceous glands. Local treatment is, however, the most valuable. In seborrhœa of the scalp, when occurring in the female, it is never necessary to cut the hair. The scales must first be removed, and this may be effected by the use of water with a solution containing two parts of soft soap and one part of alcohol. Where the scales are adherent, olive oil may be employed, thoroughly saturating the part, and allowing it, covered with a thick flannel cap, to remain over night; in the morning the scales may readily be washed off with soap and hot water. After the parts are cleansed, ointments may be applied, and among the best are those of sulphur and mercury. An ointment of sublimed or precipitated sulphur, one to three drachms to the ounce of lard or vaseline, may be mentioned as one of the most useful. There may be cases in which it is ineffectual, then an ointment of white precipitate, fifteen to forty grains to the ounce of vaseline, may be used with advantage; or the red oxide of mercury, five to twenty grains to the ounce. Tarry preparations, such as oil of cade, in the strength of one or two drachms to the ounce of alcohol, are often of service. Tar ointment is also valuable. The following may be used later in the treatment:

℞.—Ol. ricini, ... fʒij.
Acidi carbolici, ... mⱪxxx.
Alcoholis, ... fʒiv.
Sig.—Apply once daily.

It is often surprising to see how much stronger remedial applications the scalp will stand than the other parts of the body.

In seborrhœa of the face and body, mercurial and sulphur ointments are the most useful; their conjoint use, of course, should be avoided. The following lotion of sulphide of zinc may be used with excellent result.

℞.—Zinci sulphatis,
Potassii sulphureti, . . . āā ʒss to ʒj.
Alcoholis, ... fʒss to fʒiij.
Aquæ rosæ, ... fʒiv.
Sig.—Apply fifteen minutes at a time with a soft sponge. Shake before using.

In this combination a chemical decomposition occurs, in which a grayish precipitate of sulphide of zinc is thrown down.

Another valuable lotion is that known as Vleminckx's solution, the formula of which is as follows:

℞.—Sulphuris sublimati, ... ℥i.
Calcis, ... ℥ss.
Aquæ, ... fʒx.
Coque ad fʒvj, filtra, adde ol. anisi q. s.
This should be used diluted, one part to four or twelve of water.

COMEDO is a disorder of the sebaceous glands characterized by yellowish or whitish pin-point and pin-head sized elevations, containing in their centre exposed blackish points. The affection is known in popular language as "grubs," "grub worms," and "blackheads." It is found mostly on the face, back of neck, chest, and back. The lesions are usually numerous, often associated with acne and sebaceous tumors, and run a chronic, sluggish course. It occurs generally in young persons between the ages of fifteen and twenty-five years, and is often dependent upon general debility, constipation, dyspepsia, and chlorosis. The skin is improperly nourished, and acquires a thick muddy complexion. The process is confined to the sebaceous glands and ducts, consisting of a distention of the follicles with sebaceous matter. Sometimes the comedo contains a small curled-up hair, sometimes a parasite known as *demodex folliculorum*, which, however, is perfectly harmless, and is in no way a cause of the disease.

The treatment should be both internal and local. Internally, tonics of iron and arsenic, and saline aperients, may be administered; and locally, hot baths, with soap and friction. The comedones should be expressed by means of a watch-key, or, where they are very numerous, a curette may be employed with advantage. Stimulating ointments and lotions should be used, especially those containing sulphur.

℞.—Sulphuris sublimati, ... ʒiij.
Adipis benz., ... ʒij.
Vaseline, ... ʒv.
Sig. Apply at night.

Vleminckx's solution,—one part to three or six of water, or a lotion containing equal parts of sulphur, glycerine, carbonate of potash, ether, and alcohol may also be applied with good results. Attention must also be directed to regulation of any functional disturbance of the stomach or bowels that may exist.

MILIUM consists in the formation of small, roundish, whitish, sebaceous, non-inflammatory elevations, situated in the skin beneath the epidermis. They are whitish or pearl-colored, rounded or acuminate; are found for the most part on the face, eyelids, and foreheads of elderly persons, and may exist in such numbers as to be disfiguring. The lesions may undergo calcification, giving rise to *cutaneous calculi*, the product being chiefly phosphate of lime. The causes of the disease are the same as those which produce comedo and cyst. Examination shows the lesions to have no apertures on the surface, and to consist of accumulations of sebaceous matter within the glands. In the matter of treatment, electrolysis with a fine needle, or incision and the application of tincture of iodine or of nitrate of silver may be resorted to.

SEBACEOUS CYST, or WEN, appears as a variously sized, firm or soft, rounded, more or less prominent tumor, having its seat in the skin, or subcutaneous connective tissue. It is found especially on the scalp, face, back, and scrotum. There are two kinds, one with open, the other with closed ducts. The course of the development is slow. In diagnosis they must be differentiated from fatty tumors, and from molluscum epitheliale. The treatment should be radical, and consist of a removal by dissection of the cyst with its wall. Hypodermic injections of tincture of iodine may also be mentioned as useful.

HYPERIDROSIS is a functional disease of the sweat-glands, consisting in an increased flow of sweat. It may be universal or local, limited or excessive, unilateral or bilateral. It is generally met with on the palms of the hands and soles of the feet. The secretion may be so excessive that it drops from the hands, thus incapaci-

tating an affected individual from engaging in any pursuit. The secretion is not accompanied by any odor.

BROMIDROSIS, also a functional disease of the sweat-glands, is characterized by more or less sweating, and a heavy or an offensive odor. This may be universal or local, generally the latter, and usually affects the axillæ, genitalia, hands, and feet. The odor may be heavy or stinking, or be likened to that of a goat or to urine; odors, as of violets or fruits, as pineapples, are also rarely thrown off from the body. Bromidrosis when highly developed is a disgusting affection; the individual becomes a burden to himself or herself, may be kept out of employment, and naturally inclines to shun all society.

CHROMIDROSIS is an affection in which the sweat is variously colored, being bluish, blackish, reddish, greenish, and yellowish. Prussian blue, indigo, and copper have been found in the secretion. In *hæmatidrosis*, blood corpuscles are found in the sweat, and in *uridrosis* the sweat contains urea. *Phosphorescent* sweat is occasionally met with. Here the body becomes luminous in the dark. It occurs sometimes in individuals who have partaken of putrid fish, also in the late stages of phthisis.

In the treatment of diseases of the sweat apparatus, more especially hyperidrosis, tonics of iron, quinine, arsenic, and the mineral acids should be exhibited, also belladonna, atropia, and ergot. Locally, lotions may be employed, and among the best are those of tannic acid and salicylic acid in the strength of one drachm to four or eight ounces of alcohol. Tincture of belladonna, full strength or diluted, is also valuable. Boracic acid, sulphate of zinc, alum, and chloral may also be referred to as useful. The application of the lotion may be followed by some dusting powder, as starch, lycopodium, oxide of zinc, alum,—one-half drachm or more of the latter to the ounce. Dusting powders containing boracic and salicylic acids must be mentioned as being serviceable.

One of the best modes of treatment is that by diachylon ointment and olive oil, equal parts, spread on linen cloths in form of plaster, and wrapped around the affected parts, the dressing being changed twice in the twenty-four hours. In the treatment of bromidrosis the same general rules apply. In this affection, the oleate of mercury, ten or fifteen per cent. strength, may be added to the list.

CLASS II.—HYPERÆMIA.

There are many diseases of the skin which commence with hyperæmia, but pass so quickly into inflammation that they are not classed under hyperæmia. Thus, in this class are embraced but two diseases, erythema simplex and erythema intertrigo.

ERYTHEMA SIMPLEX is usually local and occurs in the form of spots and patches variously sized and shaped. It is met with chiefly in infants, and may be occasioned by some disturbance of digestion. The lesions usually last only a few hours, but may continue several days. Other forms of this disease are caused by exposure to the sun, traumatism, local irritants, and poisons.

ERYTHEMA INTERTRIGO is a hyperæmic disease, characterized by redness, heat, and an abraded surface, with maceration of the epidermis. It is commonly known as chafing, and is caused by friction between two folds of skin, occurring especially in the axillæ, groins, beneath the mammæ, and between the nates. It is usually sudden in its advent, and is found for the most part on infants and on corpulent persons during hot weather. The disease is not always a passing disorder, but may persist, sometimes, for months.

Erythema intertrigo is the only form of hyperæmia calling for treatment, and it may consist in the use of dusting powders, such as starch, Venetian talc (silicate of magnesia), or alkaline lotions, as of borax or castile soap, followed by some dusting powder. If it does not yield to such simple measures, black wash, lotions of tannic acid, boric acid, or sulphate of zinc may be employed. If it still persists, then certain other remedies, to be mentioned under the treatment of erythematous eczema, may be used.

CLASS III.—INFLAMMATIONS.

ERYTHEMA MULTIFORME is an acute inflammatory disease, characterized by reddish, more or less variegated macules, papules, and tubercles, discrete or in patches. It occurs in various forms. The commonest is the papular manifestation, *erythema papulosum*. Sometimes the lesions are in the form of a ring, *erythema annulare*. Sometimes in the form of variously colored concentric rings, *erythema iris*. At times the patches assume large gyrate forms with irregular edges, *erythema marginatum*. The disease is acute, and, as a rule, of short duration, running its course in two or three weeks, sometimes being accompanied by febrile disturbance. It is inclined to show itself in crops, and it is a peculiarity of this disease to appear as a rule first upon the backs of the hands Generally it is confined to this region. The subjective symptoms are insignificant, compared with the apparent violent nature of the inflammation. It is most frequently met with in spring and autumn, and relapses are known to occur. Comparatively little is known of its pathology. The histology of the lesions reveals nothing beyond the ordinary inflammatory changes, and authorities regard it as the result of vaso-motor disturbance. In the diagnosis it must be distinguished from herpes iris, urticaria, eczema papulosum, and erythema nodosum. Little is to be said about the treatment, as the disease usually passes off in a week or two. Active local treatment is to be avoided, as it may aggravate the symptoms.

ERYTHEMA NODOSUM is an acute inflammatory disease, characterized by the formation of rounded, ovalish, or variously sized, more or less elevated reddish nodes. There is usually some prodromic febrile disturbance, and before the eruption appears, it is difficult to make the diagnosis. The eruption makes its appearance suddenly, having preference for the forearms and legs, especially over the tibiæ, and the site of the lesions is the seat of a burning or shooting rheumatic pain. The lesions vary in size from a chestnut to an egg, are rounded or ovoidal, present a variegation in color, and attain their height usually between the fourth and sixth day, when they look shining, and are tense. They are firm and painful on pressure, so that when over the tibiæ the patient may be unable to walk. The disease may also attack the mucous membrane of the mouth, tongue, and gums.

It usually occurs in weakly or debilitated subjects, is preceded and accompanied by languor, malaise, and rheumatic pains, and is of most frequent occurrence in

females, in childhood, and in adolescence. It is closely allied to erythema multiforme, some authorities even considering it as an advanced stage of this disease. The lymphatics are often involved, and the exudation is either plastic, serous, or hemorrhagic. The lesions may be mistaken for contusions, the similarity has even led to the name *dermatitis contusiformis*. It may be further confounded with a bruise, erysipelas, and threatening abscess.

The lesions are more deeply seated and more nodular than in erythema multiforme. As the disease ends in spontaneous recovery, little or no treatment is indicated. When the febrile symptoms are marked, quinine, aconite, laxatives, and salines may be employed. Rest is important, and locally, hot water applications may be made. The duration of the disease is from two to three weeks, and relapses are not common.

Urticaria is a disease which we are liable to meet with any day. It is known popularly as *nettle-rash* or *hives*, and is an inflammatory disease characterized by the formation of wheals of a whitish, pinkish or reddish color, accompanied by stinging, tingling or pricking sensations. Its advent is usually sudden, and the lesions are variable as to size, shape, and color. They may be circumscribed or diffuse, often showing a tendency to coalesce, forming patches of a rounded, ovalish, or elongate shape, sometimes gyrate. They are soft and firm, and may rise considerably above the surface. On an individual affected with urticaria, the eruption may be evoked by passing the finger-nail over the skin.

The disease is generally ephemeral, lasting but a few hours or a day, and individual lesions are capricious and fugitive. Every part of the integument is liable to be attacked, and it is apt to go from one region to another. It may even appear on the mucous membrane of the mouth and pharynx to the exclusion of the rest of the body, and may occur at all periods of life, children being particularly liable to it. It is an acute disorder, but may be chronic by relapses.

Urticaria papulosa is a form of the disease met with among the poorly cared for children and infants. It is common in London, but rare in Philadelphia. The lesions are in the form of small papules, are very persistent, and are annoying, especially at night. Urticaria may also occur with other diseases; *e. g.*, purpura, constituting *purpura urticans*. It may assume a bullous form, *urticaria bullosa;* or a large nodular type, *urticaria tuberosa*, or giant urticaria, the lesions having an elevation of a half inch or an inch, and are found most frequently about the head.

Acute Urticaria.—The advent is sudden and is preceded often by slight febrile symptoms, languor, malaise, gastric derangement, and constipation. In a few hours the whole surface of the body may be covered with wheals. The duration is variable, and relapses may or may not occur.

Chronic Urticaria.—The lesions are the same, though less acute than in the former variety, and the disorder may last for months or years; successive crops appearing daily or at intervals. The wheals may be ephemeral or persistent, while the general symptoms are usually wanting.

The causes of urticaria are numerous and varied. Among external irritants may be mentioned: stinging nettle, caterpillars, jelly-fish, etc. Among internal causes: gastric and intestinal derangement, fish, shell-fish, certain fruits, chloral, salicylic acid, iodide of potassium, intestinal worms, menstrual and other uterine disorders, organic diseases of internal organs, spinal irritation, neuralgia, asthma, and albuminuria. The pathology of the lesions consists of an acute inflammatory process in the papillary layer, with œdema of the skin. The circulation is interfered with, in the wheal the blood being driven from the centre to the periphery. The process is largely under the control of the nervous system. In some cases no cause can be detected.

The diagnosis is easy. It must be differentiated from erythema papulosum, erythema tuberculosum, and erysipelas. In regard to treatment, it is always important to investigate the cause, and when found to be a disorder of the alimentary canal, emetics, salines, and the repeated use of aperients should be ordered. Diet should be regulated, and some alkali administered; *e.g.*, liquor potassæ. In chronic urticaria, diuretics may be employed with benefit; *e.g.*, acetate of potassium. When gouty symptoms are present, alkalies and colchicum are indicated. Other remedies which may be found useful, are quinine, pilocarpine, atropia, sulphite and hyposulphite of soda, bromide of potassium, and chloral. Change of climate may also at times be useful.

Local treatment is of importance with a view of immediate relief. This may consist of baths or lotions, the same being agreeable and cooling. Lotions of vinegar and water, alcohol, brandy, or whiskey, may be used. The baths may be alkaline or acid. Carbolic acid is an excellent remedy, so, also, thymol, one to three grains to the ounce; chloral, chloral and camphor, each one drachm to one ounce of ointment, chloroform, ammonia water, and dilute hydrocyanic acid.

ORIGINAL ARTICLES.

ON THE PATHOLOGICAL AND PRACTICAL RELATIONS OF THE DOCTRINE OF THE BACILLUS TUBERCULOSIS.[1]

By AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, AND OF CLINICAL MEDICINE, IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

The literature of the last quarter of a century, so far as it relates to pulmonary phthisis, offers a striking example of the mutability of medical opinions, and an instructive lesson for truth-seekers in the field of medicine. About twenty-five years ago, Virchow enunciated the dogma that the name tubercle should be restricted in its application to neoplasms known as miliary tubercles, or the granulations of Boyle; the phthisical products distinguished as infiltrated, crude, yellow, or cheesy tubercle having no claim to be considered as tuberculous. This dogma rested on an exclusively histological basis. It was accepted by many French and British, as well as by most of the German pathologists, and largely in this country. As a consequence, pulmonary phthisis and pulmo-

[1] Read at the First Stated Meeting of the New York County Medical Association, January 14, 1884.

nary tuberculosis were regarded as essentially distinct affections.

Phthisis, being relegated among the purely inflammatory diseases, received a variety of new names, such as broncho pneumonia, chronic catarrhal pneumonia, cheesy pneumonia, lobular pneumonia, etc. That phthisis and true tubercles were associated, in a certain proportion of cases, was admitted, and, reversing the teaching of Laennec as regards their relationship, the tubercles, in these cases, were regarded as occurring, not anterior, but secondary, to the phthisical products, being attributed to an auto-infection either from phthisical or degenerating products of some kind, somewhere within the body. Reasoning from these premises, in opposition to the results of the clinical studies of Laennec, Louis, and others, the development of phthisis was attributed often to an extension of inflammation from the bronchial tubes, and, not infrequently, to an antecedent lobar pneumonia. A peculiar predisposition to phthisis, as expressed by the terms diathesis, dyscrasia, and cachexia, was repudiated. A susceptibility to morbific agents of all kinds was alone admitted, under the name vulnerability. As practical consequences, patients affected with phthisis were treated by measures addressed to chronic inflammatory affections. Local bloodletting, counter-irritation, confinement within doors, mercurialization, and restricted diet—measures heretofore in vogue, which had become obsolete because experience had shown them to be hurtful—entered again, to a greater or less extent, into the practice of physicians in cases of phthisis.

These pathological, etiological, and therapeutical views, so widely at variance with those which had been established by the clinical studies of Laennec, Louis, and others, had their origin in the microscopical observations which led Virchow to conclude that an essential distinction exists, as regards the anatomical elements, between the ordinary phthisical products and the bodies to which he restricted the name tubercles.[1] During the greater part of the last quarter of a century, a large share of medical literature, in different countries, has been devoted to investigations and discussions either relating to, or growing out of, the dogma enunciated by Virchow. As a result of these investigations and discussions, the dogma and, of course, all deductions therefrom were at length shown to be erroneous.

It required, thus, nearly twenty-five years to emerge from errors due to a false conclusion from microscopical appearances observed in a pathological laboratory. The errors were not merely of pathological interest, but they influenced unfavorably the treatment of patients affected with phthisis. What is the lesson to be learned from this retrospect? It teaches, of course, the evils of hasty or rash pathological deductions; but I will go further and say that it teaches the importance of the clinical study of diseases as a safeguard against errors arising from exclusive attention to histological researches. Laennec, Louis, and they who followed in their footsteps, were painstaking, careful, and conscientious clinical observers. The fruits of their studies are as valuable to-day as they have been in the past, and they will remain so as long as the diseases which they studied and the human constitution continue unchanged.

In speaking thus of the importance of clinical medicine, I do not undervalue pathological researches. Of the importance of these, the subject of my paper offers a brilliant example.

A notable event in the literature of phthisis was the announcement by Villemin, in 1865, of the inoculability of tubercle. The accuracy of Villemin's experimental observations was speedily established by other observers. But the conclusion that inoculability proved the existence of a specific virus was opposed by experiments which appeared to show that morbid matter evidently not tuberculous, as well as putrescent organic substances, and those even which could have only a mechanical effect, were capable of inducing tuberculous disease in certain animals by inoculation. These apparent obstacles in the way of the recognition of a specific virus had been, in a great measure, if not entirely, removed when the discovery of a particular micro-organism—the bacillus tuberculosis—was announced by Koch in 1882.[1] The latter discovery may be said to be a sequel of that by Villemin.

Two things are remarkable in view of the recency of the announcement of Koch's discovery. It is remarkable that it should have at once excited so much interest in different countries. This has rarely been the case with past discoveries of like novelty as well as importance. It is remarkable that they who have already accepted the discovery are among those who, as practical histologists, are most competent either to confirm or disprove it.

The statement of the fact that a peculiar micro-organism, to which Koch gave the name bacillus tuberculosis, was found by him in tuberculous products, by no means expresses the length and breadth of the discovery. This fact, however, lies at the foundation of a new doctrine—a doctrine apparently in conflict with well-founded pathological truths, and of great practical importance.

Before considering its pathological and practical relations, let us inquire of what does this doctrine consist, and on what does its validity rest? Is the bacillus tuberculosis a veritable micro-organism?

The affirmative answer to this question must be based on the testimony of competent and trustworthy microscopists, and there is almost entire unanimity among these in the conclusion that the

[1] In a recent discussion at a meeting of the Berlin Medical Society, Virchow proposed to distinguish miliary tubercles and caseous hepatization as "bacillary affections." There does not seem to be any intrinsic impropriety in this name, but the unfortunate consequences of his former definition of tubercle do not afford encouragement for another attempt in the way of nomenclature.

[1] Of those who claimed that tuberculous disease in certain animals may be artificially produced by inoculation with non-tuberculous substances, Cohnheim and Wilson Fox were the most prominent and influential. As showing that, in the minds of these distinguished pathologists, the desire for truth is paramount to the pride of opinion, it is pleasant to state that Cohnheim, prior to Koch's discovery, and Wilson Fox, quite recently, have publicly made avowal that they were mistaken.

bacillus tuberculosis is a veritable micro-organism. Of this, positive proof is the reproduction of the organism by culture outside of the body.

Is the bacillus tuberculosis constantly found in morbid products, which, irrespective of its presence, are known to be tuberculous?

The affirmative answer to this question is sustained by a very general agreement among competent and trustworthy microscopists.

Is the bacillus tuberculosis found in morbid products which otherwise have no claim to be recognized as tuberculous?

So far as I know, an affirmative answer to this question is *not* sustained by the testimony of competent and trustworthy microscopists.

From these data it may logically be concluded that the bacillus tuberculosis is a peculiar parasitic micro-organism which is characteristic of tubercle. But the doctrine goes further. The nature and extent of the pathological connection of the bacillus with tuberculous disease are to be inquired into.

Is the bacillus tuberculosis the causative agent in the development of tuberculous disease?

This is an all-important question as regards the pathological and practical relations of the doctrine. Koch's discovery embraced the induction of tuberculous disease in certain animals by inoculation with the bacillus. In order for inoculability to constitute proof that the organism, *per se*, is the causative agent in the experiments, it is evident that the bacillus must be devoid of any morbific matter which might be adherent to it. This essential requirement is secured by repeated cultivations in a culture-medium out of the body. Koch found that the organism, after it had been carried through several generations, was capable, by inoculation, of inducing tuberculous disease. Assuming accuracy of the observations, this result is demonstrative proof that the bacillus, at least in the experiments on certain animals, is the causative agent in the development of tuberculous disease. The accuracy of Koch's experimental observations in this regard has not been disproved. Reasoning from analogy, and still assuming the correctness of the data, it is a logical conclusion that pulmonary phthisis, in the human subject, is caused by the presence of this parasitic organism.

This completes the doctrine of the bacillus tuberculosis. It follows therefrom that pulmonary phthisis is an infectious disease, using this term infectious in the sense in which it is at present used by most medical writers, namely, as denoting disease dependent on special causative agents, which, under favorable circumstances, are capable of multiplication indefinitely either within or outside of the body. The multiplication of the special causative agent in phthisis, takes place within the body. The disease is therefore communicable by means of the causative agent, the bacillus. The causative agent, thus, is a *contagium vivum*. If the validity of the doctrine be acknowledged, it must be admitted to be vastly improbable that phthisis is ever developed without the presence of the parasite. It may be laid down as a law in etiology, that the agency of special causes is essential in the development of all infectious diseases, and there is no reason for supposing that phthisis is an exception to this law. Another conclusion must be admitted, namely, that pulmonary phthisis, is primarily a local affection. The initial morbid processes take place in the lungs, being due to the presence of the parasite. The bacilli, doubtless, inhaled with the inspired breath, become colonized within the pulmonary alveoli. They give rise to tuberculization in the situations which they inhabit. The local affection extends in consequence of their invasion, successively, of different parts of the pulmonary organs, and the development of the disease in other situations depends on their migrations.

We are now to consider an apparent antagonism between the doctrine of the bacillus tuberculosis and certain facts derived from the clinical study of pulmonary phthisis. In view of such an antagonism, what are we to do as seekers after truth? Are we to repudiate the doctrine on the one hand, or the clinical facts on the other hand? We are to do neither the one nor the other. We are to satisfy ourselves of the truth of the doctrine, and that the clinical facts are well grounded; then, the doctrine and the facts are to be reconciled. If the doctrine be true and the facts well grounded, there must be a way of reconciliation. In reality, the antagonism is apparent only, not actual, as I shall endeavor to show. The antagonism relates especially to the existence of a tuberculous diathesis, to the well-established operation of causative agencies other than a contagium, and to a lack of clinical evidence of communicability.

Pulmonary phthisis is eminently a diathetic disease. The diathesis, that is, the predisposition, is evidently in some persons innate. How otherwise are to be explained the instances in which many children in certain families become victims of the disease—instances which are too many to be accounted for on the ground of accidental coincidence? No one who has given any attention to the statistics of this disease, can doubt that heredity is involved in the causation. That the disease is developed much oftener in some climates than in others, is certain, and it is equally certain that, irrespective of climate, insalubrious situations, a humid soil, confinement in illy-ventilated rooms, insufficient alimentation, and mental depression, exert a causative influence. No fact in medicine is better established than that age enters largely into the causation of pulmonary phthisis.

How are these facts to be reconciled with the doctrine which teaches that the efficient causative agent in the development of this disease is a contagium? And, as regards communicability, statistics have failed to prove that this disease is contagious. It is true that isolated instances seem to point to its communicability, but the analytical study of large collections of recorded cases seem to furnish evidence against, rather than for, contagion. Of those who are brought into close proximity to phthisical patients in hospitals or elsewhere, how small is the proportion who become affected with the disease! At the time of Koch's discovery, there were a few physicians who believed that phthisis

might be communicated; but the great majority of the members of the medical profession had no faith in its contagiousness. How are these facts to be reconciled with the doctrine which teaches that phthisis is never developed without the presence of a contagium vivum?

The special morbific agents which give rise to infectious diseases require for the efficiency of their causative action certain special concurrent, coöperating conditions within the body. This requirement is greater in some than in other diseases, but the statement is probably applicable to a greater or less extent to all. The special agent is an essential factor; and another, not less essential, is the existence of the requisite concurrent, coöperating conditions. The nature of these conditions is unknown, but the fact of the necessity for their existence in the causation of diseases is as certain as if they were known. We may embrace these conditions under the name predisposition. If the special causative agent be a micro-organism, it is customary to say that, like certain plants, it needs for its growth and multiplication certain peculiarities of soil. The term predisposition embraces these peculiarities. The two factors in the causation, namely, the special causative agent and the concurrent, coöperating conditions embraced under the name predisposition, in their application to yellow fever, were compared by the late Dr. Barton, of New Orleans, to the two blades of a pair of scissors; their efficiency depends on their being joined together; separated, each is powerless.

The predisposition to pulmonary phthisis involves all causes exclusive of the special causative agent—the bacillus. An innate tendency, heredity, and the other causes already referred to, exert their influence by inducing or promoting the predisposition to the disease. The predisposition is the diathesis. It may be either congenital or acquired. It may exist and afterward disappear. It may probably be removed by measures employed for that end. This last statement is of great practical importance, and will be referred to in another connection. If the predisposition be wanting, persons are insusceptible to the special cause of pulmonary phthisis. However large the number of bacilli inhaled, they are powerless, like the separated blade of a pair of scissors. If the predisposition exist, phthisis will be developed, unless the inhalation of bacilli can be avoided; and this, in most parts of the world, is impossible, so long as the disease is as prevalent as it now is. The susceptibility dependent on the predisposition doubtless varies much in degree in different persons, and at different times in the same person. The danger of contracting the disease, as it is reasonable to suppose, is proportionate to the degree of the susceptibility. It is also a rational supposition that the danger is, in a measure, proportionate to the degree of exposure to the contagion.

The views just presented are not peculiar in their application to tuberculous disease. The susceptibility to this disease, as shown by the results of inoculation, are far from being the same in all animals. It is great, for example, in rabbits, and comparatively slight in dogs. Some persons are insusceptible to the special causes of certain diseases, smallpox included. To certain of the contagious diseases the susceptibility is extinguished if the disease be once experienced. On the other hand, the occurrence of certain diseases (for example, relapsing fever), does not in the least lessen the susceptibility to their causes. Persons may be exposed many times to contagia or other special causes with impunity, the diseases becoming at length developed on exposure. In short, I have applied to pulmonary phthisis well-known truths as applied to other infectious diseases. These truths are novel, and may seem startling in their application to pulmonary phthisis, because, up to the present time, few physicians have been accustomed to look upon this disease as belonging among the infectious diseases.

I proceed to consider briefly the doctrine of the bacillus tuberculosis in its practical relations. In this division of the subject, we are to inquire into the relations of the doctrine to the diagnosis, prognosis, and treatment of pulmonary phthisis.

Of the importance of the bacilli in diagnosis, I can speak from personal knowledge. For several months I have obtained the results of examinations of sputa for bacilli in a large proportion of the cases which have come under my observation in hospital and in private practice. Not claiming to be a microscopist, it is proper to state that these examinations have been made either by my colleague, Prof. William H. Welch, or by my clinical assistant, Dr. William H. Flint, or by Dr. H. M. Biggs, Senior Assistant Physician of the Third Medical Division of Bellevue Hospital. The results taken in connection with the histories, the symptoms, and the physical signs, have satisfied me that the bacilli in the sputa may be relied upon as proof of the existence of tuberculous disease. There is abundant, competent testimony to the correctness of this statement. I am led to believe that, if repeated examinations, made with sufficient care, show the presence of the parasite, the diagnosis of phthisis is positive, and, on the other hand, if, on repeated and careful examinations, bacilli be not found, phthisis may, with much probability, be excluded. I ~~return~~ to predict that the time will soon come when, in order to corroborate the diagnosis, and as the hinge on which the question of diagnosis will turn in certain cases, microscopical examinations of sputa will be considered to be as much a matter of course as examinations of urine for evidences of renal disease. In cases of suspected phthisis, when the diagnosis is not rendered clear by physical signs, the presence or the absence of bacilli in the sputa will serve to determine either that the disease exists, or that it may be excluded. I could cite many cases which have been under my observation, in illustration of the value of this criterion of pulmonary phthisis.

So far as my experience goes, an abundance of bacilli in the sputa of phthisical patients is evidence of active progress of the disease, and *vice versa*. I am prepared to believe that in the number of bacilli found on repeated examinations, we have important data for forming a judgment in relation to prog-

nosis. I have been much interested in the study of some cases of lesions incident to advanced phthisis, as shown by physical signs denoting solidification of cavities, in which bacilli in the sputa were few or wanting. The results of the microscopical examinations of the sputa in these cases, corresponded with the history and symptoms in showing that the tuberculous disease had ceased, and that the patients suffered only from the lesions resulting therefrom. The bearing of this fact on prognosis is obvious. We may hope for the recovery, or at least, an indefinite prolongation of life in cases of phthisis in which the lungs are considerably damaged, provided the tuberculous processes of disease have ceased. I have enunciated in different publications the conclusion based on my own clinical studies, that pulmonary phthisis is a self-limited disease. The parasitic doctrine is in full accord with this conclusion. After a series of successive generations, the race of bacilli becomes extinct, probably because the local conditions for further multiplication no longer exist. In this regard, the tuberculous affection resembles other infectious diseases.

Lastly, the relations of the doctrine of the bacillus tuberculosis to the prevention and treatment of pulmonary phthisis, are the most important of the practical aspects of the doctrine.

The prevention of the disease can be effected by the accomplishment of either one of two objects, namely: First, avoidance of all exposure to the contagium; and, secondly, the removal of the concurrent, coöperating conditions in which consists the diathesis, the predisposition, or the susceptibility.

The first of these objects is not easily accomplished. Wherever there are cases of phthisis, the respired atmosphere may contain bacilli. We may be at this moment inhaling them if, among this audience, there are persons affected with phthisis. If there be a spot on the globe where there is not, and has never been, a case of phthisis, in that spot a person—no matter how great may be the predisposition—is safe. But where among the places in which persons may wish to live is such a spot to be found? It is evident that prevention by this method cannot be reduced to a degree approaching to certainty. Perhaps as safe a situation as any, exclusive of uninhabited regions, is on shipboard, provided it is certain that all others on board are free from phthisis. But we cannot enjoin on healthy persons to spend their lives at sea, especially inasmuch as we have no positive criteria of a tuberculous predisposition prior to the development of phthisis.

Preventive measures, moreover, relating to this object are not to be ignored. Assuming the existence of a tuberculous predisposition, there may be more or less exposure to the contagium, and the disease be not developed, the bacilli failing to become colonized. Exposure to the contagia of other diseases, or to infectious matter multiplied outside of the body, is by no means always followed by infection. Danger of infection is, of course, other things being equal, proportionate to the degree and duration of exposure. Hence, preventive measures, in this direction, are to be employed as far as practicable. Healthy persons should not occupy the same bed with phthisical patients, nor the same room at night, unless the dictates of duty, humanity, or affection, require that the risk of infection should be incurred. Sanitaria for phthisical patients and situations considered as favorable for those patients, should be avoided by those who are not tuberculous, in their choice of health resorts. The disinfection of sputa from phthisical patients by some simple but effective means is to be recommended. The freest possible ventilation of rooms or hospital wards occupied by phthisical patients should be secured. It is probable that not a little can be accomplished, in the way of prevention, by proper attention to these points.

The prevention of phthisis by the removal of the predisposition is a more available method. Here we labor under the difficulty of not being able to recognize with positiveness, by any criteria as yet ascertained, the existence of the tuberculous predisposition. Its existence should certainly be suspected if brothers or sisters have died with phthisis, and whenever there is reason to suppose that the predisposition may be inherited. Especially are preventive measures in this direction to be employed during the period of life when the disease is most apt to be developed, namely, from twenty to thirty years of age. Evidently, if preventive measures be practicable, it is far better to be oversuspicious of the tuberculous predisposition than to err in not having suspicion sufficiently aroused.

Ignorance of the particular conditions which constitute the predisposition to phthisis, is to be confessed, and we must, therefore, be guided by the lessons of experience and of common sense in the endeavors to remove this predisposition. These lessons teach that a dry, salubrious, uniform climate, the atmosphere rarefied by altitude, ample alimentation, life in the open air, a fair proportion of muscular exercise, protection of the surface of the body from cold, and cheerful spirits, are measures to be relied upon for this object. The measures, in other words, are those which tend to produce the highest grade of constitutional vigor. It is certain that the prevalence of phthisis would be greatly diminished by these measures; and if every member of the human family could be made to enjoy in the utmost degree the blessings of hygiene, who knows but that, in the course of time, the complete extinction of this disease might be included among the triumphs of preventive medicine.

The treatment for the arrest of pulmonary phthisis has reference to two objects: first, the destruction of the parasite, and, second, the removal of the conditions on which it depends for its existence.

Although not quite two years have passed since the announcement of Koch's discovery, many experimental observations have been made with a view to discover an effectual parasiticide which will destroy the bacilli by direct contact, either by means of inhalation, or by introduction into the circulatory system. Various substances which are known to be destructive to micro-organisms outside of the body, have been employed, such as corrosive sublimate, iodoform, bromine, arsenious acid,

salicylate of soda. Thus far they have proved ineffectual.[1]

There are three difficulties in the way of success by means of inhalation. The first is to discover the particular parasiticide. This difficulty applies alike to both methods of effecting the destruction of the parasite by direct contact. Of the different infectious diseases supposed to depend on the presence of micro-organisms, each has its own parasiticide. Mercury, for example, is an effective agent in cases of syphilis, but it has no effect upon malarial disease; and the specific agent for the latter is without effect in syphilis. For most of the infectious diseases, the specific curative agents remain to be ascertained. The second difficulty in the way of the direct destruction of the parasite by means of inhalation is, that the agent for its destruction, inhaled in the form of either an impalpable powder, a vapor, or a gas, is not likely to reach the colonies of bacilli in sufficient quantity to effect the object. The third difficulty is, that a parasiticide brought into direct contact with the bacilli by means of inhalation, in sufficient quantity to destroy them, is likely to injure the tissues, or, by passing into the blood, to induce toxæmia.

The two last-named difficulties do not apply to the introduction of parasiticides into the blood. It remains to be ascertained by experimental observations which, as yet, are but commenced, whether a parasiticide can be found capable of effecting the first object in the treatment, namely, the direct destruction of the parasite, by means of either its inhalation or its introduction into the circulation. That this object may be effected, is by no means beyond the limits of possibility, nor, perhaps, of probability. For this we must wait patiently. Meanwhile, the second object in the treatment, namely, the removal of the conditions on which the parasite depends for its existence, is not to be overlooked, nor undervalued.

Let it be borne in mind that the continuance, as well as the origin, of pulmonary phthisis, depends on two factors—the presence of bacilli and the concurrent, coöperating conditions. The disease will cease to progress whenever either factor ceases to exist. Without the conditions just named, the generation of bacilli must end. Without bacilli, there can be no tuberculosis. The bacilli are destroyed by removing the conditions on which their existence depends, as surely as by an effective parasiticide. Applying, in the plural number, the language of Shylock, "you take their lives when you do take away the means by which they live." The measures for the removal of these conditions are precisely those pertaining to hygiene, which enter into the preventive treatment, and they need not be here recapitulated.

In conclusion, I will summarize an estimate of the pathological and practical relations of the doctrine of the bacillus tuberculosis, at the present moment, by quoting the concluding paragraph of another article:

"The researches of Koch and others have extended our knowledge of the pathology and etiology of pulmonary phthisis. Their practical bearings on diagnosis and prognosis are important, and they have opened up inquiries in relation to prophylaxis which may lead to useful results. But, as regards hygienic and medicinal agencies in the treatment of the disease, we have thus far acquired nothing beyond the rational views and the lessons of experience by which physicians were guided prior to the discovery of the bacillus tuberculosis. These views and lessons remain unaffected by the discovery. In the adaptation to individual cases of phthisis, of remedies, diet, regimen, and climatic changes, we are to continue in the endeavor to judge by the light of reason and experience; and it is not less a duty now than heretofore to accumulate facts which have practical bearings, irrespective of any doctrine."[1]

FATAL CASE OF PERITONITIS,[2]

CAUSED BY PERFORATION OF THE APPENDIX VERMIFORMIS, DUE TO THE LODGEMENT OF A CONGLOMERATE MASS OF SMALL SEEDS.

BY FRANK C. WILSON, M.D.,

PROFESSOR OF PHYSIOLOGY AND CLINICAL MEDICINE IN THE HOSPITAL OF THE COLLEGE OF MEDICINE, LOUISVILLE, KY.

ON Friday, October 5, 1883, I was called in consultation with Dr. W. T. Leachman to see a young girl about 13 years of age, who, on the preceding Monday, while at the Exposition, had been suddenly seized with pain in the abdomen, located in the right inguinal region. Upon reaching home she had been put to bed and given a dose of castor oil. The next day Dr. Leachman was called in, and found her with slight fever, the temperature being 99.5°, the pulse rapid, and the respiration quickened and almost entirely pectoral. The pain was excruciating and could only be relieved by large and frequently repeated doses of opiates.

In answer to inquiries as to the possible cause of her sickness, she stated that five or six weeks previously she had swallowed a copper coin, and though she had watched closely her actions since, she had failed to find it. It was thought that possibly the coin might have lodged in some fold of the intestine, and, ulcerating its way through the walls, caused the peritonitis. A large poultice, covered with oil-silk, was applied over the entire abdomen, and opiates given in sufficient quantity to relieve the pain.

When I saw her on Friday there was considerable tympanitic distention of the abdomen, with great tenderness over the entire surface, more noticeable

[1] MM. Parrot and Martin have reported in the *Revue de Médecine* (Nos. 9 and 10, 1883) the results of experiments with a view to discover a parasiticide which will be effectual without injuring the tissues. They found that salicylic acid, sulphate of quinine, corrosive sublimate, carbolic acid, creasote, bromine water, and peroxide of hydrogen, in quantities suitable for administration, have no influence on the bacillus. *Vide* THE MEDICAL NEWS, December 22, 1883.

[2] Read before the Medico-Chirurgical Society.

in the right inguinal region, and there was dulness on percussion over an area three or four inches in diameter in the same locality. There was evidently general peritonitis most intense over the right side of the abdomen. The poultice was continued, opiates given in sufficient quantities to relieve pain, and every effort made to administer nourishment, both by the stomach and rectum. She was able to retain very little nutriment, and continued to grow worse until Monday night, just eight days from the time she was taken sick, when she died.

On Tuesday night, twenty-four hours after death, we made a post-mortem examination of the abdomen, no other portion of the body being opened. The intestines and mesentery were found extensively matted together by inflammatory lymph of recent formation. Douglas's cul-de-sac was filled with a purulent collection, and there were several collections of pus found in the neighborhood of the cæcum. The vermiform appendix was carefully examined, and upon withdrawing it two small ulcers were discovered about one inch from the extremity, which communicated with the cavity, and which had no doubt allowed the escape of fecal matter into the peritoneal sac. Near these openings was found in the appendix a small hard mass which, upon removal, looked like a cherry-seed. Subsequent microscopic examination of it by Prof. Holland and myself revealed it to be a collection of small seeds, as of the blackberry or strawberry, matted together into a hardened mass. This mass, or one like it, was no doubt the cause of the inflammation. A careful search in the entire course of the intestinal tract was made for the copper coin without discovering any trace of it. It had, in all probability, been passed without her knowledge.

This case illustrates very clearly the fact, that there may be greater danger in eating blackberry or strawberry preserves than in swallowing cherry-stones, peach-stones, or coins.

MEDICAL PROGRESS.

Bacilli of Cholera Infantum.—At a recent meeting of the Berliner Med. Gesellschaft Dr. A. Baginsky made a report on the bacilli of cholera infantum, which he has found both in the dejections and in the intestinal mucous membrane. In the dejections, along with numerous other micro-organisms, Baginsky found masses of zoöglœa, whilst the Peyer's patches in the upper part of the small intestine were filled with microbes containing bacilli, the wandering of which into the submucous tissue could be frequently recognized. Here, also, the zoöglœa masses could be made out as well as in the dejections.—*Allg. Wien. mediz. Zeitung*, Nov. 6, 1883.

Napelline in Facial Neuralgia.—M. Grognot has recently reported an interesting case showing the efficacy of napelline in facial neuralgia. The case was that of a young girl who, for three years had had violent periodic facial neuralgia, though independent of menstruation. Aconitine was tried repeatedly, and failed to give permanent relief. Finally, napelline was administered in pills containing one-thirtieth of a grain, ten pills being given daily. After a few hours the pain disappeared. Two months later another attack was successfully treated.

It is well known that amorphous aconitine is more often successful than the crystalline. This is due, says Grognot, to the fact that the napelline contained in the amorphous variety has been removed from the crystalline.—*L'Union Méd.*, December 6, 1883.

Influence of Quinine on Heat-production and Heat-loss.—While Binz, Naunyn, and Quincke concluded from their observations that the antipyretic action of quinine is due to a diminished production of heat, Wood has recently asserted that after the administration of quinine there is an increased loss of heat, amounting to about sixty per cent., and, at the same time, an increased heat-production of about forty-three per cent.

H. Arntz has still more recently (*Pflüger's Archiv*, xxxi. S. 531) investigated the subject on normal and fevered rabbits, and draws the following conclusions:

The use of quinine has, with few exceptions, no influence on the loss of heat through the skin. In rabbits with septic fever there is a considerable decrease of oxygen consumption, and when immersed in a bath of the temperature of the body all loss of heat ceases. This is not observed in the case of non-fevered animals. *Centralbl. f. d. med. Wissensch.*, November 24, 1883.

The Couveuse, or Artificial Nurse.—This apparatus was introduced into the Maternité at Paris, by Tarnier, in 1881. It is composed of a wooden box, the walls of which are about four inches thick, and filled in with sawdust. The box rests upon a pedestal. The height of the whole couveuse is thirty-eight inches, length twenty-eight inches, depth thirty-four inches. It is divided into two compartments by a central division. The lower compartment contains warm water; the upper is for the infant. The metal case holding the warm water almost entirely fills the lower compartment. Between the walls of the box and the metal case is a free space for the circulation of air, which enters from the bottom of the apparatus, and, after circulating, escapes through apertures in the top.

The infant is placed in the upper compartment. It is separated from the water-tank by an air-space, and communicates with the exterior by two openings, one for the escape of air, the other for removing the infant when necessary.

A thermo-siphon is attached to the water-tank, which heats the water by a spirit-lamp. The temperature is determined by placing a thermometer by the infant. The water is removed by the stopcock at the bottom, and introduced through the upper tube leading from the thermo-siphon. The temperature is kept at a mean of 86° F. Dr. Budin has attached an electric alarm, in case the heat becomes too great.

At the Maternité the infant is generally placed under the care of a nurse, as the mother is usually in another ward. When the infant is born before term and is very feeble, it is fed on pure asses' milk, from a spoon or glass. The infant is clothed just as other nursing infants. The linen is changed five or six times a day, and a daily bath is given.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 19, 1884.

OÖPHORECTOMY AND HYSTERECTOMY FOR UTERINE FIBROMATA.

AT the recent Congress of German Naturalists and Physicians, held at Freiburg, as we learn from the *Archiv für Gynäkologie*, Bd. 22, Heft 1, 1883, DR. WILDOW read a paper on "Castration for Uterine Fibroids," in which he gave the statistics of 66 operations, with 12 deaths, or a mortality of 19 per cent. Of these, Lawson Tait lost 5 out of 26, and Hegar lost 5 out of 21. In the discussion which followed, Freund stated that he had had 6 cases, with 1 death, and Müller, also, reported 6 cases, with 1 death. In the majority of the cases in which the result was known, the bleeding soon ceased, and the menopause and the diminution in the size of the growth soon set in. In several instances the menses continued, a fact that had been observed by Schatz after double ovariotomy.

In a paper contributed to the *Transactions of the American Gynecological Society*, vol. vii., 1883, Mr. J. KNOWLSEY THORNTON discusses the relative value of hysterectomy and oöphorectomy for the cure of uterine fibroids, and he refers to 76 cases of the latter operation, with a mortality of 15, or 19.73 per cent. If, however, the death-rate be based upon the results of surgeons who have had the most experience, it will be found to be greatly decreased. Thus, Tait has had 38 cases, with 33 recoveries; Hegar, 21 cases, with 16 recoveries; Savage, 14 cases, with 14 recoveries; Thornton, 8 cases, with 8 recoveries; Freund, 6 cases, with 5 recoveries; and Müller, 6 cases, with 5 recoveries. In other words, 93 cases in the hands of skilled operators afford 81 recoveries, and 12 deaths, or a mortality of 12.90 per cent. Of 221 hysterectomies, on the other hand—under which procedure are included all cases in which the uterine cavity is laid open, and more or less of its wall removed along with the fibroid, with or without excision of one or both of the ovaries—performed by Péan, Sir Spencer Wells, Billroth, Thornton, Bantock, Koeberlé, Schroeder, Hegar and Kaltenbach, Savage, and Thomas, 131 recovered, and 90, or 40.72 per cent., perished.

Having thus shown that oöphorectomy is attended with far less risk than hysterectomy in the hands of practised surgeons, Mr. Thornton asserts that supravaginal hysterectomy in the class of cases under consideration still remains a most formidable operation, and subjects the patient to the risk of ventral hernia. That this operation, which includes the removal of the tumor, the uterus, and the uterine appendages, is a most grave one cannot be doubted; but that it is not formidable to one thoroughly skilled in abdominal surgery is shown by the wonderful experience of Dr. Thomas Keith, which may be found in the *British Medical Journal*, for December 8th. Of 25 supravaginal hysterectomies performed by this surgeon during the past ten years, only 2 were fatal, and the success is the more astonishing when we learn that all but three were hospital cases. The average weight of the tumors was seventeen pounds; seven of the cases were most trying and difficult to complete; and the bladder had to be dissected off in not less than six. All of the 23 women who recovered enjoy excellent health, and in not a single one is there the slightest approach to a hernia. And yet, despite these unparalleled results, this modest, honest, preëminent surgeon in his branch, thinks that his death-rate can be reduced.

The mere removal of the ovaries does not always entirely stop menstruation, or the growth of the tumor. Mr. Thornton, in his comments upon the failures, states that, in addition to the excision of the ovaries, the dilated tubal and ovarian arteries and veins must be tied to insure success. Unless the chief blood supply be cut off the operation may fail. The uterine arteries are seldom very large; they are difficult to get at, and in tying them there must be great danger of including the ureters. So great is his belief in the arrest of the chief blood supply being the important factor in the cure, that he should in the future prefer oöphorectomy with ligation of the vessels to enucleation through the vagina for intramural and submucous tumors, unless they are already becoming exposed by thinning or necrosis of the mucous membrane.

It is to be regretted that Dr. Keith has not entered fully into the details of his manner of operating. Most of his operations were extraperitoneal, that is, the stump was secured outside of the belly by a very large clamp. He finds Kœberlé's instru-

ment most useful in half extra- and half intraperitoneal cases. The broad ligaments were almost always separated off the tumor and tied separately. Extensive enucleation was often necessary in order to place the wire as low down as possible when there was no cervix. As the bladder often rises as high as the umbilicus, and as it is not always easy to distinguish its edges, if the "stupid direction be followed that it be emptied before the operation is begun;" it should be left full. In his operations the carbolic spray is discarded.

THE DWIGHT INSURANCE CASE, AGAIN.

In the interesting review of the Dwight insurance case, which appeared in our last number, from the pen of Dr. H. C. Wood, we find nothing to alter the opinions given in a former issue (December 22). Even the unanimity with which experts for the defence adhered to the opinion that Dwight died from strangulation, effected by a cord around his neck, does not shake our convictions, and their consistency in adhering to the opinions once formulated does not necessarily increase our confidence in their accuracy. Consistency is a jewel, most truly; but the moral courage necessary to change opinions for the sake of truth is an altogether higher quality. We do not therefore sympathize with the felicitations on the constancy with which the experts adhered to their opinion.

Their uniformity of opinion, moreover, does not strengthen a fact which rests on individual judgment. This, Dr. Wood seems conscious of in the following observation: "If the facts sworn to by Dr. Swinburne are as he alleges, I can but reiterate my opinion expressed upon the stand, that there is no room for doubt as to the cause of death"—that is, by strangulation. It appears that the experts assembled by Dr. Flint in Philadelphia had all reached this conclusion, and from the same premises—the observations of Dr. Swinburne. With the exception of Dr. Wood, these experts, it further appears, did not give evidence at the trial, and they now disappear from the record.

With prepossessions in favor of Dr. Swinburne, and believing him quite incapable of any voluntary or designed misstatements, we nevertheless see in his testimony the evidences of strong partisanship. He saw an indentation in the neck, produced, as the undertaker testified before the Coroner's jury and at the trial, by bending the neck and by the pressure of the chin supports used. Dwight's neck was short, thick, and bearded. If we add to the effect of bending such a neck the sugillation, and the fixation of the parts by freezing, we have an adequate explanation of a condition which to a mind possessed with the idea of fraud, might appear to be produced only by a cord.

Those post-mortem conditions supposed to be due to death by strangulation, were referred by us to morphine poisoning; an opinion which was based upon a careful study of the sworn evidence given at the Coroner's inquest. The experts for the defence reply that the administration of morphine was not mentioned at the trial, and, therefore, should not figure in any review of the case. We have no purpose to subserve except the interests of the truth and independent journalism, and they demand that the facts in evidence, developed under oath at the Coroner's inquest, must not be ignored in the study of this remarkable case.

The claim that the testimony before a Coroner's jury is "confidential," is not entitled to serious consideration. In what year of grace did a Coroner's investigation assume the mysterious attributes of a Star Chamber Inquisition? A Coroner's court must, necessarily, in a free State, be entirely open and public; and, moreover, the facts there developed constitute "legal evidence" and a criminal is deprived of his liberty under its procedures.

If the testimony before the Court varies from that given before the Coroner, is not the credibility of the witness correspondingly injured? As a rule, if the mere facts of a case are sought for, they are to be obtained in a truer and fresher state from the Coroner's inquest, which is promptly held after the death. Later, in the process of "sifting" and case-preparing, in the partisanship, in the spirit of contest and desire of triumph, facts are modified and interpretations put on them not warranted by their original meaning. It is therefore important to get the facts from that period when they had not been tampered with by opposing counsel, or interpreted by partisan experts. In the testimony given before the Coroner, we find information regarding the influence of morphine in determining the fatal end of Dwight, and a further review of that testimony more than ever impresses us with the importance of morphine as a factor in the result.

On the day and evening of Dwight's death, he had taken somewhat more, it is probable, than three grains of morphine; the last dose administered hypodermatically, about two hours before death. As he had a singular insusceptibility to the soporific effect of morphine, it was given him in a lavish manner. He had declared that he could take it in any quantity, and that there need be no apprehension about giving it to him; hence the remarkable quantity administered on the day of his death, in anticipation of the supposed congestive chill, due on the following day.

That there was danger in the use of so much morphine, notwithstanding the apparent indifference of the nervous system, is shown in an experience of

his physician, who testified before the Coroner that on one occasion, Dwight falling asleep under the effect of considerable doses, "his breathing was hurried, and I had a little doubt in my own mind," *i. e.*, regarding the effect of the morphine. It is this action on his respiratory system to which we refer the unfortunate termination of the case. On the night of his death, and two hours before the end, Dwight had received a subcutaneous injection, and afterwards expressed himself as "comfortable," and disposed to sleep. Whilst his friend who watched sat reading, about two hours after this last dose, he heard a sound indicative of difficult breathing, and approaching, found Dwight in the agony of death, from respiratory failure.

Any one familiar with the action of morphine when given subcutaneously, will recognize in this one of the modes of dying from this agent. Those, of course, who have no other conception of morphine narcosis than stupor and slowly failing respiration, may find it difficult to appreciate a termination in which respiratory spasm and paralysis are coincident. The cases in which death ensued in the mode here described are, unfortunately, too numerous to permit of doubt.

DIPHTHERIA AND PSEUDO-MEMBRANOUS SORE THROAT.

THE practitioner of ordinary experience soon recognizes a decided difference between that grave constitutional disease known as diphtheria, in which a false membrane starts at one point and extends in various directions, and a form of angina also accompanied by high fever and painful deglutition, to which are added one or more white patches, mostly on the tonsils. These, however, do not spread, and within seventy-two hours generally drop out, leaving a clean depression, which rapidly disappears. Coincidently with the disappearance of the white patches, the fever and other constitutional symptoms decline and recovery is rapid.

It is well known, too, that some physicians are in the habit of terming this latter condition diphtheria, and acquire not a little ill-founded reputation among their immediate adherents for invariable success in the treatment of this fell disease, although they have had to do with a harmless local condition, often accompanied, it is true, by disproportionately intense general symptoms, but which would have disappeared without treatment in a couple of days.

What, however, is this circumscribed, white, circular patch, a quarter to a third of an inch in diameter, which at the end of forty-eight hours drops out and leaves the clean, punched-out cavity referred to? It consists of the mucous membrane, including its epithelial and subepithelial layers, infiltrated with white blood-cells, cemented by coagulated fibrin, and permeated by countless bacteria. It is, therefore, from the standpoint of morbid anatomy and pathological histology, false membrane in the strict sense of the word, as much as the false membrane of true diphtheria and croup. At the same time, it is evident that the disease is not the constitutional affection known as diphtheria, but contrasts strongly with it in its purely local nature, its harmlessness, its curability, and short duration. It is evident, too, that we have no name in medical terminology so definitely associated with this condition as to make it invariably evident to all readers and listeners what is meant.

The terms acute follicular tonsillitis, ulcerated sore throat, and diphtheritic sore throat, have all been used to describe it. It has also been called *herpes* and *eczema tonsillaris*. Were it certain that one of these white spots always encircles a follicle of the tonsil, as it often does, and as is proved by the presence of a minute hole in its centre, the first term would be perhaps the best. But this is by no means invariably the case. The term ulcerated sore throat is unsatisfactory because it does not indicate the local peculiarity. With regard to the last-named title, while the tonsils are subject to the same vesicular or pustular inflammations as the cheeks and gums, resulting in the painful gray ulcers, surrounded by red areolæ, with which we are all familiar, these ulcers are very much more rare on the tonsils, and the process is not that to which we allude.

The term diphtheritic sore throat, as distinct from diphtheria, is objectionable because it suggests an alarming and dangerous constitutional disease, the mere idea of which is sufficient to excite a panic. This objection cannot be made to the term pseudo-membranous sore throat, while the scientific accuracy of the term cannot be questioned. There is a sore throat—a tonsillitis and a pharyngitis—but along with this is a condition, which morbid anatomists the world over have agreed to call a diphtheritic or croupous exudation, the result of a circumscribed, intense inflammation, which is distinguished from the catarrhal inflammation which accompanies it by this patch of false membrane.

It appears, therefore, that the term pseudo-membranous sore throat should be adopted, and we should teach our patients generally, what many of the more intelligent ones already know, that there is a vast difference between diphtheria and pseudo-membranous inflammation; that the former is a general disease with a local product, and that the latter is a mere local disease with a local product, which, although identical in structure with the former, has a very different significance.

PERMANENT CATHETERISM OF THE ŒSOPHAGUS.

KRISHABER, of Paris, in a paper read at the International Medical Congress, 1881, recommended that in carcinoma of the œsophagus, a soft tube be passed, through the obstruction by way of the nares, and be permanently retained, for the double purpose of feeding the patient and inducing dilatation of the contraction. That the suggestion was a most happy one, was demonstrated by two cases in which the patient was nourished, respectively, for one hundred and sixty-seven and three hundred and five days by this method of treatment.

In a discussion on the management of malignant stricture of the œsophagus, which took place at the Clinical Society of London, in 1881, MR. DURHAM narrated a case in which a tube had been retained for four months, and the patient was doing well. In vol. xii. of *St. Thomas's Hospital Reports*, which has just been issued, MR. CROFT again calls attention to the subject, and gives the details of two cases in which life was prolonged, respectively, for one hundred and eight, and one hundred and forty-nine days. In the latter, indeed, the subject might have survived some weeks longer had the tracheotomy-tube, which had been worn for seventy-three days, been sufficiently long to reach below the level of the growth which was pressing on the windpipe.

The five cases to which we have now referred, show conclusively that the œsophagus tolerates a tube indefinitely, and that alimentation by this means insures a prolongation of life, which it is too generally thought is attainable only by operative interference. More than this, not only is the procedure a perfectly safe one, but it preserves life much longer than cutting measures, the average existence of the five cases having been one hundred and seventy days, and is a far better result than has been afforded by gastrostomy, œsophagostomy, or internal œsophagotomy. Hence, when the œsophagus is pervious to a tube, this method of treatment should be tried before an operation is resorted to.

The early use of the permanent tube for alimentation is also indicated in cicatricial stricture of the thoracic portion of the œsophagus which resists dilatation with bougies, as well as in cases of compression of the canal by an enlarged thyroid gland, mediastinal glands, or carcinoma of the larynx. Whatever the cause of the trouble may be, a tube of medium size, say No. 17 or 19 of the French scale, should be selected, and be carefully and patiently passed, when it may be retained by a strip of plaster across the cheek. It should be changed every four or five days, and should be rendered aseptic before reinsertion to prevent the conveyance of putrefactive agents into the stomach. As the introduction of a tube by the mouth is far easier than by the nose, the former route should be preferred for a few days, or until the œsophagus has become accustomed to its presence, when it may give way to the latter, which is attended with less discomfort to the patient.

CONGENITAL DISPLACEMENT OF THE HEART.

AN interesting report on a case of congenital displacement of the heart has recently been made to the Academy of Medicine of Paris, by a commission composed of MM. Marey, Sappey, and Vulpian. The subject was a woman, and was the second which has been thoroughly studied in France. There was diaphragmatic hernia, the heart projecting through an opening in this muscle, and protruding under the skin of the epigastrium, where it could be seized with the hand.

The result of the examination is to confirm the prevailing views of the phenomena of the heart's action as determined by the study on animals. Thus it is proved that the impulse of the heart is systolic in time, and not diastolic, as was formerly claimed by many, and is still held by a few clinicians. It was also ascertained that, whatever be the derangement of rhythm, the two ventricles always coincide in their contraction. Such derangement was produced in the patient by emotional causes in a prolonged examination. The only difference demonstrated in the two ventricles was in the force of contraction, that of the left being of course the more energetic.

The position of the heart behind the sternum did not permit the accurate study of the auricles as compared with the ventricles. This was, however, done in a second case examined by MM. Paul and François-Franck, in 1877, wherein it was noted that the auricular systole immediately preceded the ventricular, which is also a confirmation of the results of the delicate experiments by Chauveau and Marey upon animals.

The confirmation, afforded by these rare cases of malposition, of the results of experimentation upon animals, adds another to the many reasons for continuing this practice, to which we are indebted for so much of our accurate knowledge in physiology.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

A LARGE number of the profession in the city of New York, desiring not to be misrepresented by the action of the Medical Society of the State of New York, and of the Medical Society of the County of New York, in reference to the Code of Ethics, have organized a new society under the title of "The New York County Medical Association," and have made the National Code a part of their by-laws. They have thus formally placed themselves in affili-

ation with the profession throughout the United States, and its representative body—The American Medical Association.

The first meeting of the new society was held last Monday evening under the most auspicious circumstances. There was a large and representative attendance, and the scientific work was inaugurated by an extremely valuable paper by Dr. Austin Flint, Sr., on the pathological and practical relations of the doctrine of the bacillus tuberculosis, which we have the pleasure of laying before our readers in full in this issue.

The new society will enjoy the confidence and best wishes of the profession throughout the country.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 11, 1883.

THE PRESIDENT, ROBERT F. WEIR, M.D., IN THE CHAIR.

TRANSVERSE WOUND OF EXTENSOR TENDON OF FINGER; SUTURE.

DR. A. C. POST presented a patient with the following history:

November 3, 1883, George Moore, aged nine years, was brought to my clinic, with the index finger of his left hand flexed at a right angle at the articulation between the first and second phalanges. The patient had no power of extension, although there was no rigidity of the articulation. There had been a transverse incision over the back of the joint five weeks before. The external wound had healed. I made a free longitudinal incision over the dorsal surface of the finger, and found the tendon divided transversely throughout nearly its whole breadth, there being a very narrow strip undivided on each side. The proximal end was full and loose, the distal end was somewhat atrophied, and adherent to the periosteum. I excised the margin of the opening, and then brought the divided ends together with fine sutures, after which I secured the finger in a position of exaggerated extension to a dorsal splint passing over the hand and forearm.

10th.—I dressed the wound, removed the sutures, and found the external wound almost perfectly united.

December 8.—On removing the dressings, I found the finger straight, and the patient had the power of flexion and extension. I did not, however, allow him to make extensive movements.

NEURALGIA OF SECOND BRANCH OF THE TRIGEMINUS.

DR. F. LANGE presented a patient, about forty years of age, a tailor, who suffered from neuralgia of the second branch of the trigeminus on the right side, which resisted for a long time the usual external and internal remedies and applications, until finally the patient submitted to an operation, which was performed in March, 1882, after the method of Leucke, modified by Braun and Lossen, and consisting in an osteoplastic resection of the zygomatic arch and bone, and finding the nerve in the depth of the spheno-maxillary fossa, at its exit from the skull, and besides a separation of the nerve at its exit from the infraorbital foramen, and extracting the anterior piece from the base of the skull to this point. He was unable to destroy the spheno-palatine ganglion, and so far the result had been permanent. Anæsthesia followed the operation immediately, and was complete also on the corresponding side of the palate. The patient at present has a certain kind of formication, which he describes like the crawling of worms, but has no real pain. The operation was performed by making a horizontal incision along the upper edge of the zygomatic arch, extending to the external angle of the orbit, and then a perpendicular one downward over the base of the zygoma, and with a fine saw separating the zygoma from its attachment to the superior maxilla, directing the saw so that the blade is more parallel to the sagittal plane, in order to prevent subsequent disfiguration through depression of the separated bone.

Then by bone scissors the arch was cut across half an inch in front of the meatus auditorius externus. This triangular flap of skin and bone was pulled downwards, and then the spheno-maxillary fossa laid open, the temporal muscle drawn backward, and the nerve found after some adipose tissue had been pulled aside or removed. In the patient presented, the operation did not offer any peculiar difficulty; but Dr. Lange presumed that it was probably on account of his lack of fat, and could readily conceive that sometimes in stout, fleshy persons the operation might be very tedious. He was able to see the internal maxillary artery, but had no disagreeable interference by hemorrhage. The wound healed entirely by first intention, and, as an accident, the rubber drainage-tube was healed in. After a time, the tube was cut out. The result, so far as disfiguration went, was rather gratifying, and also with respect to the recurrence of the disease. Dr. Lange did not think that any other operation afforded the possibility of excising the nerve to so great an extent and with so little danger and disfiguration as the one described. For some time the patient had slight difficulty in opening his mouth in consequence of inflammatory contraction of the temporal muscle, but at present he has no difficulty which prevents him from taking his food, though the excursions of the jaw are not normal yet. The little wound by which the nerve was exposed at its exit from the infraorbital canal had hardly left a visible scar.

DR. BRIDDON asked what objection there was to performing the anterior operation first, and reserving the more extensive operation in the spheno-maxillary fossa for a return of the disease.

DR. LANGE said that he did not regard the operation as a severe one.

DR. BRIDDON remarked that he saw the more extensive operation performed several years ago, and it was exceedingly tedious and very unsatisfactory, as he thought. He was unable to state what the result was.

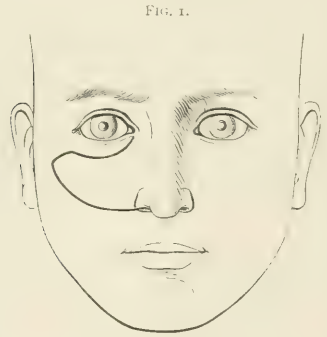
DR. A. G. GERSTER then read a paper on

OSTEOPLASTIC RESECTION OF THE UPPER JAW FOR PROSOPALGIA, WITH THREE CASES.

Total extirpation of the upper jaw, as a preliminary measure for facilitating the removal of massive nasal

polypi, was first successfully done by Syme, in 1832 (*Ninth Report of the Edinburgh Surgical Clinic*), and having been adopted by the then reigning French school of surgeons, remained the standard measure in the operative treatment of the above-mentioned disorder. The happy idea of a more conservative procedure was first conceived, and successfully executed by von Langenbeck, in the year 1859 (*Deutsche Klinick*, 1859, p. 471), when he extirpated a large retro-nasal polypus through an aperture made by what he designated an osteoplastic resection of the nasal process of the superior maxillary and the os nasi. The ease afforded in the removal of the polypus by this step, and the primary healing in of the resected parts led to further trials, and, in 1861, another more extensive and also successful case was reported by von Langenbeck in the *Deutsche Klinick* (1861, p. 281). This case consisted in the temporary removal of the superior portion of the upper jaw, without injuring the hard palate, the alveolar process, or the velum palati, followed by the excision of a large fibroid of the pterygo-palatine fossa. The steps of the operation were as follows: A curved incision, its convexity looking downward, commenced in the nostril, and extended outward and upward to the middle of the malar bone, the periosteum being divided at one stroke. The masseter was cut away from the edge of the zygomatic arch, and the buccal fascia was divided. The lower jaw was now drawn aside, and the tip of a keyhole saw being introduced into the pterygo-palatine fossa, the upper jaw was sawn through horizontally above the alveolar process, the cut through the bone following the line of the cutaneous incision to the nostril. A second incision, commencing at the nasal process of the frontal bone, was carried outward along the lower margin of the orbit, to join the first incision at the middle of the malar bone. Now the orbit was entered, and the eye-

FIG. 1.



Showing the cutaneous incision.

ball pushed up; then the frontal process of the malar and the zygomatic process of the temporal divided; finally the orbital plate of the superior maxillary severed transversely as far as its junction with the lachrymal bone. Thus, the resected jaw remained attached by skin and periosteum only to the nasal bone and the nasal process of the frontal bone, and could be easily pried out of its bed by the aid of an elevator, the above-mentioned uninjured parts serving as a sort of hinge. The tumor was readily removed; the profuse hemorrhage ceased spontaneously, only one ligature, that of the spheno-palatine artery, being required. The resected parts were now replaced, some difficulty being met with in overcoming their tendency to protrude. Wire sutures and a compressory bandage finally effected this end. The cutaneous incision healed almost entirely by adhesion; the bone was found to be immovable on the eighteenth day after the operation.

The value of this truly conservative idea was soon recognized, the operation became well established, and was quite often executed by various surgeons in Germany.

The first one to widen the field of this procedure was Nussbaum, of Munich, who, in 1863, had to deal with an obstinate case of supra-infraorbital neuralgia, of traumatic origin (A. Fr. Bratsch, *Bayer. Intelligenzblatt*, 1863, p. 461, Case No. 13) in a woman of thirty-eight years. Numerous neurotomies of both the supra- and infraorbital nerves had been performed during the five years preceding her admission to Nussbaum's clinic. In the course of the subsequent two years the cicatrices were repeatedly excised without improvement; finally, the common carotid was deligated, the ascending ramus of the lower maxilla was trephined in order to permit of the exsection of portions of the inferior alveolar, the mental, the mylo-hyoid, and lingual nerves. This led to necrosis and removal of the ascending ramus, but produced a pause lasting five months, after which a relapse occurred, for which von Langenbeck's osteoplastic operation was performed, with temporary success, the observation not extending over more than a few months.

The adaptation of this operation to neurectomy did not attract any attention—at least found no imitators. Billroth, then of Zurich, having excised, in April, 1864, a piece of the infraorbital, one inch and a quarter long, in what he designated "the ordinary manner"—by which Malgaigne's method is meant—and the patient's sufferings not being alleviated, conceived the idea of exsecting the mentioned nerve from the foramen rotundum forward, by the aid of von Langenbeck's osteoplastic operation. He believed himself to be the first one who had thought of this plan; but on studying up the history of neurectomy, he found that Carnochan, of New York, had preceded him in carrying into effect a similar plan; and also Nussbaum, in executing the identical procedure which Billroth had thought of. Griesinger, who felt a personal interest in the patient, was deterred by the operation, and merely advised the removal of some sensitive portions of the corresponding alveolar process, which was done accordingly in May, 1864. The operation was followed by a quiescence of the attacks extending over ten months. The affection reappeared then, and in February, 1866, Billroth's original plan—osteoplastic exsection of the superior maxilla—was successfully performed, and the nerve was cut away close to the foramen rotundum. The operation can be done in an exact manner, without serious hemorrhage. The wound healed kindly. The exsected nerve was found to be fully regenerated, and in every respect normal. Meckel's ganglion was not removed. In the ensuing months of April and May, branches of the third division of the fifth pair became the seat of neuralgia, and required sections of the buccinatorius and mentalis nerve. In July, 1867, the common carotid was

deligated, with temporary benefit, this lasting till January, 1868, when another relapse drove the patient into Niemeyer's clinic at Tübingen, where the constant current again relieved him. Here the history stops.

From Billroth's case up to my three operations, no mention of the method as adapted to neurectomy is found in literature.

The late Professor Wagner, of Königsberg, in Prussia, devised the simplest and least incisive method by which the foramen rotundum can be exposed. He entered the orbit and laid bare its floor, then pried off the lamina of bone serving as a roof to the infraorbital canal; then, by a suitable hook, he raised the nerve out of its bed from alongside of the uninjured artery, and following it up towards the round foramen, cut away successively all its branches, and finally the trunk. The integrity of the antrum was thus preserved, yet phlegmon and erysipelas set in in almost all of Wagner's cases. This circumstance puzzled him a good deal, and he attributed it to neuro-paralytic influences. That the operation is difficult and unusually subtle, on account of the confined space, is evident. In cases of a narrow and deep orbit, or where the artery was unfortunately injured, it became almost impracticable, as one of Wagner's own cases (No. X.), König's case, and a third case demonstrated, which I had an opportunity to witness here in 1878. It must be conceded, however, that Wagner's final results, as regards the tardiness of the relapses, were very good.

The second method to be considered is that devised by Carnochan, of New York. It has its merits, but it labors under the disadvantage of also affording, in cases of a small proportioned facial skeleton, insufficient space for a sure removal of the entire nerve. Aside from the circumstance that a portion of the superior maxillary must be sacrificed in this method, it is undeniably excellent in suitable cases, and where a large trephine can be employed, it gives plenty of space and light.

As the third mode of procedure I have to mention Brun's plan of resecting the malar bone, dividing the muscles presiding over mastication, and thus approaching the nerve from the temple. It is in many ways unsatisfactory and mutilating, like Carnochan's operation, the wound is narrow and deep, and manipulation of the nerve very difficult. Yet a respectable number of cases have been operated on in this manner with fair success.

As an important modification of Brun's method, Leucke's procedure has to be mentioned, in which the malar bone is not sacrificed, but only temporarily exsected and turned aside, thus admitting the operator to the temporal and pterygo-palatine fossæ. Especially in the presence of a deep layer of adipose tissue and of large masticators, the wound must be very inaccessible.

As the fourth and last procedure, we have to mention preliminary osteoplastic resection followed by removal of the entire nerve. None of the preceding methods can compare with this as regards the space and light it affords, and the ease with which the infraorbital nerve can be removed in its entirety. It sacrifices no part of the superior maxilla, and, as statistics prove, is not more dangerous than any one of the preceding methods. With a few modifications, it deserves to be employed in cases not suited for Wagner's method, and merits further trial and development as applied to the alleviation of the terrible sufferings of prosopalgia. Advisedly, I do not use the word "*cure*," since love of truth compels me to admit that our ability to cure prosopalgia is just as uncertain as the knowledge of its pathology is unsettled and unsatisfactory.

The cases as observed by me were the following:

Case I.—Peter Deuker, æt. 36. His trade, that of an oven-builder, necessitates his frequently entering bakers' ovens to make repairs. On emerging from a very hot oven, he is liable to be exposed to sudden changes of temperature. He said that he had been suffering off and on for eighteen years. In 1877, neurotomy in front of the right supraorbital foramen was performed by a surgeon with temporary benefit. Large doses of quinine and salicylic acid also modified the attacks, inasmuch as they became shorter and less severe. In 1878, a remission of three months was brought about by a number of subcutaneous injections of one ninety-sixth of a grain of aconitine, repeated every two hours. At the end of this period mild attacks recommenced, first at long intervals, later more frequently; the hypodermic use of morphine was resorted to, until the patient had become a confirmed morphine eater. The attacks had become more frequent and more severe in spite of the anodyne, and his family attendant directed him to the Mt. Sinai Hospital, where he was admitted May 10, 1881. I found on a well-built frame a somewhat flabby skin and muscular system, the internal organs normal, the patient anxiously avoiding motions of the jaws. On the slightest provocation, such as articulation, chewing, swallowing liquids, or touching any portion of the cheek or lip, the patient's face became distorted and cyanotic, his left eye bloodshot with a copious flow of tears, and while his hands were pressed nervously to the anterior surface of the upper jaw, his body was bent low down, and a number of deep moans escaped his chest. The attacks lasted from thirty seconds to two minutes. There were two painful spots; one exactly over the left foramen infraorbitale, the other at the naso-labial junction. The teeth of the upper jaw were the seat of strong irradiating pain during the attack; the lower jaw and tongue were also somewhat affected this way; the palate was free.

Immediately on admission, treatment by the constant galvanic current was instituted, but did not produce any notable effect; hence, after forty-eight hours' preparation, an exsection was resolved upon, the anamnestic signs pointing to a neurosis, of a peripherical origin, the presumable seat of the affection being in front of the superior alveolar branch of the nerve-trunk.

In selecting the method by which this end should be accomplished, the difficulties encountered in a case of Wagner's operation, witnessed by me, were very vividly remembered. Flooding of the field by blood, soiling of the speculum—hence want of light and space, and especially the impossibility of actually following up and exposing to view the central end of the nerve situated between the foramen rotundum and the infraorbital canal, led me to abandon this method.

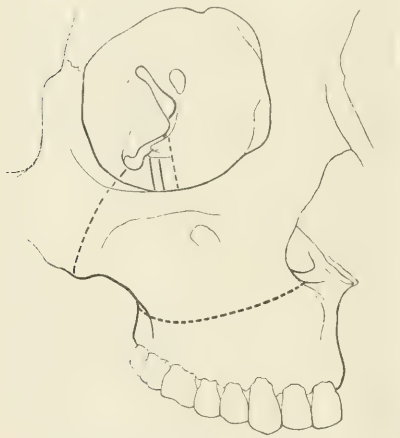
The objections to Brun's or Leucke's procedures were also great. The powerful masticators of the patient promised to give a good deal of trouble, causing a very deep wound, the possibility of injuring the internal maxillary artery in which, and the ensuing difficulty of dividing the nerve with any amount of certainty, caused me to abandon these methods also. Compared with Carnochan's operation, the temporary resection had the advantage of not mutilating, of giving decidedly

more space, and hence more certainty of accomplishing the chief end of the operation—that is, certain removal of the possibly longest piece of the nerve.

The circumstance that the method was not much tried as an aid to neurotomy was rather an incentive than anything else to new trial, and to a widening of our experience in the treatment of such an intractable disease as prosopalgia.

Accordingly, on May 12, 1881, the operation was performed, strictly after von Langenbeck, as far as the incisions are concerned, with one modification. In studying the bearings of the operation on the object in view, I found that the section through the frontal temporal processes of the malar bone could be advantageously substituted by a simple division of the middle of the malar bone. The injury would be lessened, and yet ample space would be afforded for attacking the nerve. In addition to this, the infraorbital foramen being exposed, the nerve was divided about two-eighths of an inch in front

FIG. 2.



Showing lines of section by the keyhole saw.

of it. In sawing through the superior maxillary, the hemorrhage was considerable, especially when the nasal mucous membrane was severed, but never alarming, and ceased spontaneously. No difficulty was encountered in turning the resected block out of its niche, and the nerve was seen to slip easily out of the infraorbital canal, and was lying at full length on the bottom of the wound. The alveolar and dental branches had been necessarily torn off. The trunk of the internal maxillary could be seen pulsating in the posterior part of the wound, covered by the periosteum stripped off the tuberosity of the maxilla. To expose the foramen rotundum fully, standing portions of the orbital plate of the maxillary bone had to be removed by forceps, then the nerve was grasped, and easily cut off close to the foramen. No ligature was required. The parts having been thoroughly mopped with an eight per cent. solution of chloride of zinc, were easily replaced, and the cutaneous wound closed with catgut sutures. A small drainage-tube was passed into the spheno-palatine fossa, leading out beneath the zygoma. No dressings were applied. Anæsthesia—by chloroform—was never full, except while the first incisions were made, and the blood entering fauces and larynx was readily expectorated. The length of the exsected nerve was one inch and seven-eighths; the time consumed, one hour.

On recovering, the patient at once touched his cheek, and was delighted at the absence of pain. Anæsthesia of the corresponding parts was present; the return of sensation was ascertained on the fifth day about the ala nasi, on the twelfth over the foramen. Bloody serum oozed out of the tube for about a week, then gradually the discharge became sero-purulent, and scanty, so that the tube was removed by the end of the second week. No fever and no local reaction followed, and the cutaneous wound healed by adhesion. The resected part had become immovable in the fourth week. The neuralgic attacks ceased immediately after the operation, and the patient was discharged from the hospital to resume his occupation. In the winter of 1882–83 slight attacks commenced to manifest themselves again, about once a week, the point of the most intense pain being the upper lip, near the ala nasi, and the irradiation to the teeth of both upper and lower jaws of the right side more marked than ever before. I directed the patient to a neurologist for treatment in May, 1883, but both medical and galvanic therapy proving quite futile, and the attacks gaining in violence, the patient implored me to relieve him by an operation. It seemed pretty certain that extensive regeneration of the nerve must have taken place, the dissection of which out of the cicatrix in which it needs must be embedded, promised to be a difficult task. Weighing all the circumstances, Carnochan's procedure seemed to promise most success, enabling me to expose the entire length of the infraorbital canal and Meckel's ganglion. Being readmitted, the patient was put under the influence of chloroform on June 16th, and a crucial incision exposing the foramen infraorbitale, a number of threadlike nerves were found to radiate from it. The antrum being opened by the aid of the trephine, the infraorbital canal was exposed, and a slender, irregularly shaped cord of varying diameter could be dissected out of it. The posterior wall of the antrum was broken out with a fine chisel, and Meckel's ganglion, together with the internal end of the nerve, was exsected with forceps and scissors. The removed cord proved to be composed of nerve tissue. To make sure of the destruction of the nerve as far as possible, the blunt point of a thermo-cautery was inserted into the foramen rotundum and the parts thoroughly seared. The patient recovering, complained of constant violent pain in the jaw, although the skin was found to be quite anæsthetic. In spite of a free use of hypodermic morphine injections, he spent a wretched night, the attacks being now more frequent and violent than ever, the intervals between them never exceeding five minutes. This gloomy aspect of the case continued till the discharge from the wound, which was lightly filled with iodoform gauze, commenced to be unmistakably purulent, which took place on June 19th. The highest temperature—100.5° F.—was recorded at this date, and the night was spent tolerably well, with two injections of morphine. The two nights following

the 19th were spent comfortably with the aid of one injection of morphine. On the morning of the 21st several sharp attacks were noted. Two more attacks came in the evening of June 22d, requiring an injection. Day and night of the 23d were spent painlessly and very comfortably, no morphine being required. The discharge from the deep part of the wound was purulent and copious, but the skin was never inflamed. From this time on the case did well, the attacks not returning. By July 16th there remained only a fistula, into which a probe could be still passed to a distance of two and an eighth inches. Very light formication, with tenderness, appears once in a while in the course of the second branch; lately the patient had some pain in the course of the third branch.

Case II.—Catharine Diemer, widow, æt. 42, admitted to the German Hospital, January 2, 1882. She is stated to have suffered from paroxysms of intense pain in the upper lip and the right alveolar process for two years, no cause for the same being known to her. She had all the teeth of the right upper jaw extracted one after the other, although they were sound. All this had no influence on her sufferings. The pain radiated into the ear; she never had had otorrhœa. She had been under treatment for three months in the German Dispensary for a circumscribed necrosis of the alveolar process of the second malar, undoubtedly due to the last tooth extraction. The sequestrum was removed when loose, and a fistula leading into the normal antrum was found. The alveolar process had become much atrophied, and was seen to be invested by normal mucous membrane. Dr. Gruening kindly consented to examine her ear on January 6, and found a normal drum, no perforation; acuteness of hearing slightly diminished, pointing to a chronic otitis media; the Eustachian tube free. The necessary incidental manipulations did not produce any attack. Probing of the antrum by the fistula, touching of the alveolar process, and chewing always caused acute pain, which, however, was also liable to occur spontaneously, especially at night. All other resources being exhausted, a neurectomy was decided upon, and was carried out in the German Hospital on January 19, almost in the same manner as in the first case. Profound ether anæsthesia was maintained only while the cutaneous incisions were made. Owing to their slight proportions, the sections through the facial bones were easy and rapid, the hemorrhage at first somewhat copious, but ceasing spontaneously. In the light of the experience gathered in my first case, the division of the orbital plate of the superior maxillary was so modified as to run in the antero-posterior line, from a point of the infra-orbital margin midway between the lachrymal duct and the infraorbital canal, backward and parallel with this canal to the inferior orbital fissure. Thus injury to the nerve and the lachrymal duct was avoided, and the slight tuberosity marking the inner side of the posterior end of the infraorbital canal, the chief obstacle to a free exposure of the spheno-maxillary fossa was gotten out of the way. On turning out the resected mass, the nerve was seen to slip easily out of its canal, and could be readily followed to and cut away at the foramen rotundum, the removed portion measuring one inch and three-fourths. The hemorrhage was throughout controlled by short compression. The wound was closed by catgut sutures, and capillary drainage of the spheno-maxillary fossa by a few strands of catgut was employed. The cutaneous incision healed throughout by adhesion; the place where the catgut drainage lay, continued to discharge a slight amount of serum for two weeks, then closed. Anæsthesia was fully established immediately after the operation, but the time of the return of sensibility was not marked. The attacks had ceased, and did not return till March, 1883, when she again complained of pain in the upper lip, the attacks being of a mild character and of short duration, and easily controlled by small doses of morphine.

Case III.—Jacob Kahn, dry-goods clerk, æt. 63, a well-built and well-preserved man, who was unable to name a cause for his complaint. The first series of severe attacks of facial pain occurred in November, 1879, and lasted for four weeks. Its seat was at the point of exit of the left infraorbital nerve on the face, the pain radiating into the upper teeth, the lower eyelid and left ala nasi. It was reduced by local injections of morphine, and a pause of three months followed. Since the spring of 1880, the paroxysms became somewhat more frequent, were most easily produced by mastication, but were controlled by morphine. In the spring of 1882, the attacks grew more severe, and the patient sought relief in an institute established for the treatment of nervous complaints, where he was subjected to a prolonged course of medicinal and galvanic therapy; but no improvement following he became discouraged, and having been admitted to my ward at Mt. Sinai Hospital, begged for operative relief.

The attacks were most severe in the evenings, were readily produced by touching the lower eyelids; there was a punctum dolens a little above the foramen infra-orbitale. The upper teeth and palate were free, irradiation of the pain being noticed only along the track of the supraorbital nerve. In the absence of any signs pointing to a central cause, exsection of the nerve was decided upon, and carried into effect on August 30, 1882, under chloroform. The steps of the operation did not differ from those in Case II., except that the massive frame of the patient's head made the bone-sections rather laborious. The hemorrhage was about the same as in the former cases up to the moment when the saw, having cut through the entire superior maxilla, entered the nasal cavity, when it suddenly became very profuse. Ice-water was thrown into the nares, but failed to check the hemorrhage, wherefore it was decided to hasten the remaining steps of the operation. The malar bone and orbital plate of the superior jaw were quickly divided, and the resected parts were turned out of their bed, and then the source of the profuse hemorrhage became apparent in a laceration, by the saw, of a very turgid erectile body, covering the turbinated bone. The thermo-cautery soon converted this erectile tissue into a dry eschar, and the operation was finished in the usual manner. The time consumed was forty minutes. Meckel's ganglion and one inch and a half of the nerve were removed. Catgut sutures, drainage, and a light compressive dressing completed the work. The operation was followed by prompt relief, and the cutaneous wound healed by first intention, no fever appearing, but the nose continued to discharge pus for a considerable time, and finally the skin became reddened over the line of section through the malar bone. A small puncture in the cicatrix being made, about three weeks after the

operation, the probe detected a rough surface; and subsequently, in January, 1883, a sequestrum corresponding to the temporal side of the section was extracted, the defect being marked by a deeply retracted cicatrix. Up to date, the patient remained free from facial pain.

Dr. Sessel kindly examined the nerve removed from Case I. at the first operation, and also that from Case II., and found both normal in appearance. In Case III. the specimen was lost. The proposed modifications, that is, sawing through the middle of the malar bone instead of dividing the frontal and temporal processes of the same, then, instead of Langenbeck's transverse, an anteroposterior (sagittal) section through the orbital plate of the upper jaw on the inner side and parallel to the infraorbital canal will shorten the operation and will materially increase the facility of access to the most central portion of the nerve.

It is far from my intention to urge the propriety of this operation in every case of supraorbital neuralgia, and the report on the three cases in this paper was rather inspired by the desire of testing the value of a somewhat untried procedure, and to increase the number of available means for combating a treacherous enemy. As long as the true nature of prosopalgia remains unknown, the employment of any means, and of every means, must be fair and permissible, however empirical and unscientific they may appear to be.

DR. F. LANGE would merely say that, starting with the principle to cause as little lesion as possible, he thought the certainty with which prompt union of the wound could be expected was greater in Leucke's operation than in the one which Dr. Gerster had described, because any septic influence which may follow opening of the nasal cavity and its appendages is excluded. He also thought that the thoroughness with which the surgeon was able to remove the branches of the nerve after its exit from the skull, was greater in Leucke's operation than in the one described by the author of the paper. It seemed to him that it must be quite difficult from the front to reach with certainty the sphenopalatine ganglion, although he had had no practical experience in the method. Finally, in comparing the result of the operation in the patients presented, from a cosmetic point of view, one must evidently decide in favor of Leucke's operation.

DR. T. M. MARKOE said that his experience had been limited to a single case, and in which he performed the operation through the antrum. He found no difficulty in detaching the nerve from the canal in which it lies in the superior maxillary bone, and, holding the nerve with a pair of forceps, he was able to trace it back with the end of the scissors, and succeeded in cutting off the nerve not so far back as the foramen rotundum, not so far back as the point where the two short branches go to Meckel's ganglion, but close to that point, and he felt that he cut off the nerve posterior to the two posterior dental branches, those in which relapse would seem most likely to take place. The operation was difficult and very tedious by reason of inability to get light at the bottom of the cavity, nevertheless, he felt quite sure that he cut the nerve at the point mentioned. The result was extremely satisfactory, but the entire case impressed him unfavorably concerning neurotomy in these cases. The case began as one of neuralgia of the inferior maxillary nerve, for the relief of which he trephined the inferior dental canal some two years before, and removed about one inch of the nerve, and the cure was satisfactory. After a few paroxysms the pain entirely subsided, but finally it returned in the second branch, the infraorbital, and it was for the relief of this relapse that he performed the operation on the superior maxillary nerve above described. The patient was entirely relieved by this second operation, and Dr. Markoe saw nothing of him for nearly three years, when he returned, saying that he had not had pain in the region of the distribution of the infraorbital nerve, but was then suffering intensely from supraorbital neuralgia, and refused to take any further chances of recovery by operation. In other respects the patient was entirely healthy, and there was no reason to suspect that the affection had a central origin.

DR. GERSTER then presented the patient, upon whom he operated in May, 1881, and he said he was aware that this method would have to be rarely employed, but as it may be useful in another instance, and is adapted to the removal of the second branch of the trigeminus, he thought it was worthy of the effort which it requires. That was the only object which he had in bringing the operation forward. He was sure that Luecke's method was preferable in many cases, while in other cases Carnochan's method would be the better one to resort to; but there must be cases where the method which he had described will be the best, either as the first operation to be performed, or as the last resort.

As regards the question of the healing of the external wound, since the introduction of antiseptics this was a question of much less importance than formerly. The omission of opening the antrum is not of much advantage, as already shown by Wagner's experience, which, to be sure, was gained before the days of antiseptic precautions. What seemed to him most curious was the circumstance that, after having removed the entire nerve from the infraorbital canal, sensation returns so quickly in those parts which are innervated by the second branch. Perhaps this may be explained by some filaments of sensitive nerve passing back by way of the vidian nerve to the facial, and thus distributed to the skin of the face.

DR. W. S. HALSTED remarked that in the reproduction of almost the entire superior maxillary nerve, the infraorbital canal might play the part of the "tubular suture" of Gurlt and Vinlair; the divided ends occupying a so-called "virolage."

DR. J. W. HOWE was unable to understand the advantages which the operation described by Dr. Gerster had over that performed by Dr. Carnochan.

DR. GERSTER said the chief advantage which the operation had over all other operations was that it gives a great deal of space and light, and taking all the cases together as they come, it afforded better opportunity for manipulation in the bottom of the spheno-maxillary fossa.

DR. HOWE thought that there could be no great difficulty in dissecting out the branches of the nerve in Carnochan's operation, and cited one case which he had last winter. The only difficulty which he experienced was in determining whether or not he had to deal with Meckel's ganglion, and he asked whether there was any special appearance or condition by which Meckel's ganglion could be distinguished from a little mass of

cellular tissue and bloodvessels. The case in which he operated was one of seventeen years' standing, accompanied by spasmodic contraction of the muscles of the face. The pain was relieved very much for two weeks after the operation, and it then returned, but without spasm. A drainage-tube had been passed through the canal, and this was injected with a strong solution of chloral, which diminished the pain, and since that time the patient has been comparatively free from suffering; at least, has not had any violent pain whatever.

DR. LANGE said that in the patient presented it was rather easy to trace the branches arising from the trunk of the nerve down to the spheno-palatine ganglion, probably because the patient was a very favorable one so far as a scanty amount of fat was concerned. It seemed to him also that the nerve, so far as it had been exposed in the cadaver presented by Dr. Gerster, was not reached so immediately at the foramen rotundum as it was possible to do in Leucke's operation; and it also appeared to him that a few of the thin branches of the nerve were passing down, which might be easily overlooked, and the nerve cut just in front of these fibres, and in that way the operation be performed less thoroughly.

THE PRESIDENT said that three years ago he had opportunity to present to the Society a case of persistent infraorbital neuralgia which had been cured by Carnochan's operation. The patient was seen two years afterward, and there had been no return of the pain. In this case, Wagner's operation had been previously performed by Dr. Seguin, who had had the patient under treatment for a long time. The first operation was accomplished without difficulty, and the nerve was divided probably not much further back than the posterior margin of the orbital plate. The patient was relieved for a time, but as there was a recurrence of the symptoms, an opening was made by him into the antrum with a chisel, and the inferior wall of the canal opened up by means of slender scissors, and the posterior wall of the antrum broken through by the blunt end of the same instrument. The remains of what was supposed to be the nerve, but which proved to be cicatricial tissue, to which the posterior portion of the nerve was attached, was seized with the forceps and held taut, and by means of a little, forked, blunt hook, carried onward to the foramen rotundum, the nerve was traced out and there divided with scissors. The operation was aided very materially by the use of reflected light from the head-mirror. Healing was rapid, and no constitutional reaction took place, and the deformity following the operation was very trifling, indeed. In fact, he thought that the more severe osteoplastic operation should be reserved for the more obstinate cases. Carnochan's operation has advantages over that described by Dr. Gerster or Leucke in ease of performance, freedom from hemorrhage, and lessened deformity. He could conceive of the possibility of necrosis occurring after both the osteoplastic operations, and also the possibility of mastication being interfered with in Leucke's operation. Under such circumstances, Carnochan's operation should be the first to be resorted to.

The question raised by Dr. Howe is a pertinent one. The ganglion cannot always be recognized. Dr. Weir was unable to recognize it in his case, and other surgeons had been unable to recognize it, although the extraction was accomplished, as shown by paralysis of the palate immediately after the operation.

The President also thought it a point worthy of note that one of Dr. Gerster's cases proves the possibility of a good deal of hemorrhage which interferes with seeing the different anatomical structures.

DR. LANGE remarked that one advantage which Leucke's operation possessed was, that hemorrhage is quite insignificant, and also the disfiguration is very much less than that left after any of the other operations. He would emphasize the statement that Leucke's operation involves much less surgical interference than does Carnochan's, or that by temporary excision of the jaw. There is, in fact, only the lesion of the zygoma, which is comparatively unimportant. So far as he knew, the process of healing had been favorable.

THE PRESIDENT asked if suppuration and inflammation should occur, would there not be more or less impairment of the muscles of the jaw?

DR. LANGE said he should think so, and that in some cases a certain degree of difficulty in mastication had followed the operation, but not sufficient to make it especially uncomfortable for the patient.

DR. T. M. MARKOE said that in thinking of these cases for many years past, he had been strongly impressed with the feeling that if it could be shown that these most severe and more radical, more perfect operations for neurotomy, were certainly successful in curing the disease, then they would be justifiable, but his impression was that the operations which had been described by Dr. Howe, and by himself, were very much less dangerous, less severe, and produced results which at least would compare favorably with those which had been recorded of the more severe operations referred to by Dr. Lange and by Dr. Gerster. It may be a less perfect operation, but he could conceive that if the scissors fell outside of the posterior dental nerve, all had been accomplished that could be done by exsection of the nerve, and he did not believe that it is necessary to destroy Meckel's ganglion. His own feeling had been that these severe operations did not offer so much better prospect of success as to justify their performance, but at the same time he did not wish to dogmatize upon the subject.

DR. H. B. SANDS said that within a year he had had occasion to perform Leucke's operation, not for the purpose of curing neuralgia, but with the intention of removing a tumor which was supposed to be situated in the spheno-maxillary fossa. The tumor was found where it was supposed to be, but was so extensive and so firmly attached that the operation for its removal was abandoned as impracticable. In that case the wound did well, and the bone became consolidated without necrosis. There is now noticed—about nine months after the operation—considerable difficulty in opening the mouth; but he believed this not to be due to the operation, but to an increase of the size of the tumor. He was certain that the operation proposed by Dr. Gerster, as well as the one referred to by Dr. Lange, excelled all other operations in the ease and certainty with which the parts lying in the spheno-maxillary fossa were exposed to view. Many years ago he performed von Langenbeck's operation, for the removal of a tumor situated in the spheno-maxillary fossa, and found that the end was accomplished without difficulty. He

should think the nerves in the same region might be removed with equal ease.

DR. E. L. KEYES reported

A CASE OF DEATH BY ETHER,

occurring in a colored boy, upon whom he was operating in Bellevue Hospital for exsection of the knee-joint. The patient was about twelve years old, and was apparently in perfect health, except the disease of the knee, which had existed for a number of years. He took the ether at the hands of one of the house staff, and there was no untoward symptom for an hour or more. Dr. J. D. Bryant was present, and after the operation was substantially completed, he felt the patient's pulse, pronounced it excellent, and left the room. About a minute later, the gentleman who was administering the ether said that something was wrong, called attention to the fact that the boy was breathing faintly, and that the pulse had disappeared from the wrist. Dr. Keyes at once resorted to all the usual measures for resuscitation, such as hanging the head over the table, artificial respiration, hypodermic injections of ether, ammonia, brandy, faradization of the diaphragm, strapping the extremities, etc., and these efforts were continued for forty-five minutes, but without avail, as the boy was dead. Dr. Keyes thought that the boy was probably dead before he had time to resort to any measures for resuscitation. The autopsy was made by the house surgeon, who reported that all of the organs were normal. All the internal organs were intensely congested, and the heart was empty, having stopped in systole. The ether used was that manufactured by Powers & Weightman. The quantity was nearly one pound. There was no mucus in the larynx. The patient had not vomited or attempted to vomit; everything seemed to be going on nicely, when suddenly death occurred by the heart.

DR. LANGE said that the only sad experience with ether he had ever had was in a female patient upon whom he had operated for strangulated umbilical hernia. She had a weak heart at the beginning of the operation. A fit of vomiting occurred; the heart's action ceased, and also respiration. Tracheotomy was immediately performed and the trachea sucked out, but life was extinct.

DR. SANDS thought it important to distinguish between those cases in which death occurs slowly from asphyxia and those in which it occurs suddenly from cardiac paralysis. In the latter class of cases it seems doubtful whether there would be time to resort to any measures for restoration, as death takes place sometimes almost instantly. If transfusion could be done in time, it would be indicated in some cases. He recalled two cases of death from ether which occurred in the New York Hospital. One case was that of a stout, healthy man, who, in the use of a pruning-knife, accidentally wounded his right carotid artery, and nearly lost his life upon the spot from profuse hemorrhage. He was brought to the hospital in a state of exhaustion. Dr. Willard Parker immediately came to see him, called a consultation, and proceeded to expose the injured vessel. In that case Dr. Sands remembered that he had his finger upon the patient's pulse, which became imperceptible immediately after the incision had been made through the skin. The operation was suspended for a few minutes; some restorative was given, the pulse was again felt, and the operation was proceeded with. Then a second time the pulse stopped, the face became pale, respiration ceased, and all attempts at resuscitation proved unsuccessful. In that instance death was due to the excessive action of the ether upon a heart already enfeebled by loss of blood, and therefore it might perhaps have been averted by a preliminary transfusion.

The other case occurred in the service of the late Dr. Allin, who was about to remove a tumor of the upper jaw from an old woman. The patient was in the sitting posture, and in that case also, although the face had become somewhat livid from ether, just after the incision was made through the skin, before much blood escaped the pulse stopped, and the heart's action was not resumed. The suddenness with which death occurs under such circumstances is very appalling, and seems to give little encouragement for the employment of any attempts to restore animation. He believed that in Dr. Keyes's case death had already taken place when failure of the pulse was noticed.

THE PRESIDENT said Dr. Allin's case excited a great deal of attention at the time, and observations determined that many of the deaths from ether occurred in connection with operations about the jaw and neck. This fact subsequently received a more scientific explanation from Schiff, who showed that when animals were anæsthetized, pinching the neck would arrest the heart's action and respiration. Still, it was well known how safe ether is; while chloroform kills one in twenty-five hundred, ether kills only one in twenty-five thousand. Perhaps this low mortality with ether might be explained by the fact that were it not for the warnings which ether gives, by stertor, etc., death would take place more frequently than it does.

DR. POST said that the only two fatal cases which he had seen with the administration of ether were those in which operations for the removal of tumors of the neck were being performed, which caused considerable embarrassment of respiration. There was no blood nor vomited matter to account for the fatal termination.

The PRESIDENT added another case which came under his observation while he was an interne in the New York Hospital—that of a double incarcerated scrotal hernia of immense size, which could be previously partially reduced, though usually filling the scrotum. The house-surgeon gave ether, and forced up the contents of the hernia into the abdomen, and the man ceased to breathe. Nothing was found on the autopsy to explain the sudden death, and the fact that the abdominal cavity was compelled to receive more than it was accustomed to, and thus the action of the diaphragm interfered with, was received as the probable cause.

DR. L. M. YALE referred to a collection of seven thousand cases of anæsthesia produced in one of the English hospitals, and in all the instances where alarming symptoms had occurred it had been noticed that the patients who had been rolled upon the left side recovered, while those who were rolled in the opposite direction died. Whether or not this was a general law was not stated, and he was unable to say.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, January 14, 1884.

THE PRESIDENT, WILLIAM DETMOLD, M.D., IN THE CHAIR.

THE First Stated Meeting of this Society was held last Monday evening, at the College of Physicians and Surgeons, New York. The first business in order was an

INTRODUCTORY ADDRESS

by THE PRESIDENT, in which he remarked that in welcoming the gentlemen present, he supposed it would be proper to state the object in view in the formation of the Association. It was well known that in the profession in New York there was going on a conflict which partook somewhat of the nature of a family quarrel; and family quarrels—like religious wars—were proverbially bitter and fruitless. The religious war of the Reformation in Germany lasted for thirty years, and then came to an end only because each side was exhausted. Yet it was a fact that neither party had gained anything by the conflict. He wished to state at the outset, however, that this Society did not intend to carry on the warfare in the profession. A large and respectable proportion of the medical men of New York reverently adhered to the Code of Ethics of the American Medical Association; and even admitting, for the sake of argument, that there might be some defects and shortcomings in it, they were not willing to abandon it. The opposite party was bent on destroying or emasculating this Code, which we earnestly desire to preserve. There might be honest differences of opinion among the members of the profession about certain points; but there could be no difference of opinion as to the fact that when the medical profession of the United States were met together in their representative assembly, the profession of the Empire State was excluded from the seat of honor to which it was entitled. It was the desire of the members of this Association that the medical profession of New York should no longer be placed in such a false position. They had not come together pledged to uphold the old Code any more than they had come pledged to uphold the laws and Constitution of the United States. The one was taken for granted as much as the other. This was a matter understood. Nor were they pledged to fight the other party in the profession, since they proposed to remain members of the County Medical Society, although that body had trampled under foot something which they held sacred. They had simply formed an Association which, together with similar societies throughout the State, could send delegates to Albany for the purpose of forming a State Medical Association, by means of which the profession of the great State of New York might once more become represented in the American Medical Association, whensoever and wheresoever that national body met. In conclusion, he would only say that it was intended that the papers presented to the Society, and the discussions participated in by its members, should be of the highest scientific value.

PROF. AUSTIN FLINT, SR., then read a paper on

THE PATHOLOGICAL AND PRACTICAL RELATIONS OF THE DOCTRINE OF THE BACILLUS TUBERCULOSIS.

(The paper appears in full on page 60 of THE NEWS.)

Dr. Flint was received with enthusiastic and prolonged applause, and before he commenced the reading of the paper he remarked that he considered it no small honor to be the first to present a scientific communication to this Society, and that he heartily congratulated it on the auspicious manner in which its career of usefulness had been inaugurated.

DR. WILLIAM H. WELCH in opening the discussion said that, personally, he was fully in accord with the views expressed in the paper. He had only one suggestion to make, and that was, that negative testimony in this case was of but little value as compared with positive. The fact that no bacilli could be found in any given case, especially if only one examination for their presence was made, did not prove that tuberculosis did not exist; while, on the other hand, if bacilli were found, it was proof positive of the existence of the disease. Repeated examinations, performed with great care, should be made when the early stages of tuberculosis were suspected, and great caution was to be observed in drawing conclusions from the apparent absence of the bacillus. The finding of the bacillus, he believed, established the diagnosis with absolute certainty.

DR. E. G. JANEWAY stated that he wished to corroborate what Dr. Welch had said. He was a firm believer in the existence of the bacillus and in the contagiousness of phthisis. Long before the brilliant discovery of Koch he had had his mind directed towards the infectiousness of the disease, and the latter had offered a practical solution of the matter which was entirely satisfactory to him. He had seen tuberculosis in certain families where there was nothing to explain its presence except the idea of contagion. Where there was no hereditary tendency or congenital taint whatever, he had known three or four members of a family to succumb to the disease. The lack of belief in the contagiousness of phthisis, he thought, led many physicians to neglect making proper inquiry as to whether patients had not been exposed to infection. He then proceeded to relate a case which he said he had already published, but which was of so striking a character that he would venture to repeat it. It was that of a young man suffering from pulmonary tuberculosis, who had lost three dogs in succession with all the symptoms of the disease; the animals having been in good health at the time that he purchased them. It was ascertained that he was in the habit of taking the dogs to bed with him (he owned but one at a time), and that they slept in such a position as to cause them continually to inhale his breath. Dr. Janeway remarked that he did not know of any case of the disease among dogs in which more plausible proof of its contagiousness was afforded. Physicians from different parts of the country had frequently mentioned cases to him which seemed to point strongly to a specific contagion. One, as he recalled, had told him that he had known of twenty-five members of the branches of a single family being attacked with tuberculosis.

Another point of importance was, that in members of a family in which it had appeared, who were themselves supposed to be free from it, the disease sometimes existed in a latent form and made very considerable progress before it was detected. Thus, in a family in which the mother and a sister and brother had died from phthisis, he was called to see a young woman who was suffering from hæmoptysis, and on making an examination of the chest of another sister, who had never complained of any trouble, he found a more marked tubercular condition than in the one who had had the hemorrhage. The French writers mentioned a case in which a man

was successively married to four wives, all of whom died of phthisis, the husband himself also finally dying of the disease. He fully agreed with what Dr. Welch had said in regard to negative evidence. In the early stages he had often found it very difficult to get sputa from patients at all. In the sputa of the same patients, after the disease had become more fully developed, he had in some instances found bacilli. One failure, as Dr. Welch had remarked, ought not to make us exclude phthisis. He would allude to only one other point. That day he had been at the post-mortem examination of a patient in whose lungs was found a considerable amount of cheesy degeneration. Three and a half years ago he had hemorrhage from the lungs, and the physician who attended him at that time found disease at the apex of the left lung; a fact which was afterwards entirely forgotten. In another case, where the patient died from gall-stone, the evidences of past tuberculosis were found, though it had been eighteen years since he had suffered from cough and expectoration.

DR. GEORGE PEABODY remarked that he also was fully in accord with all that had been said on the subject, and that he could only add that some corroborative evidence was afforded by the treatment devised by Kurchman, of Germany, several years ago, viz.: The use of antiseptic masks, through which the patient breathed in cases in which the disease was largely situated in the larynx. This plan he had himself tried in certain hospital patients, who had expressed themselves as greatly relieved thereby, and who had persevered in wearing the masks, notwithstanding the weather was then quite hot, on account of the relief afforded by them. In some instances the cough was markedly diminished, in some the expectoration, and in some the night-sweats, while in still others all three symptoms were benefited.

DR. NELSON related what he thought was a significant case, in the present state of the subject of tuberculosis. A gentleman who was troubled with cough and expectoration married a lady who was at the time in the most perfect health, but who not long afterwards was attacked with phthisis, and died, the husband having recovered.

Another member said that in 1868 he removed sixteen ounces of pus from the pleura of a young lady twenty-three years of age, and hermetically sealed the external wound. A few months afterward she died of tuberculosis. The remaining members of the family, which consisted of the father, mother, a sister, and two brothers, were at that time in good health; but in less than two years the entire family had been swept away by phthisis. Within a month after the death of the young lady mentioned, her sister became affected and soon died; and before a year had elapsed both the mother and father were dead. The elder brother was the next victim, and finally the younger brother succumbed. Before the death of the first daughter the family removed to a more salubrious location, immediately adjoining Central Park, and from the first they were surrounded by the best hygienic conditions. This striking history he had also reported to the Academy of Medicine.

DR. WILLIAM H. WELCH then presented

A SPECIMEN OF HYDATID TUMOR.

This was a large echinococcus cyst of the spleen, which he said was of considerable interest on account of its rarity. The patient in whom it was found was a German who died in Bellevue Hospital from superficial external burns. No previous history of disease could be obtained, and as the tumor was only accidentally discovered at the autopsy, the clinical aspect of the case was, of course, defective. No other pathological condition was discovered. The growth was attached to the hilus of the spleen, and was apparently in the gastro-splenic omentum. No external swelling seemed to be caused by it, and it was covered by the intestines; the transverse colon passing directly over the tumor. In the books it was often put down as a point in the diagnosis of enlargement of the spleen from any cause, that there would be complete flatness extending over a greater or less area, on account of the intestines being underneath the spleen. In this instance it was seen that just the opposite was the case, and during life there would undoubtedly have been tympanitic resonance over the seat of the tumor, from the fact of the transverse colon passing above it. There was a large fibrous capsule, almost entirely devoid of cells, and some calcareous deposits. On making an incision the capsule was found to contain about four ounces of clear fluid, and after it had escaped it was found that there was a large cyst in the centre which had collapsed. This was the mother-cyst, while surrounding it there were at least two hundred daughter-cysts. The method of development was, therefore, exogenous, which was much less common than the endogenous, in which the daughter-cells grow within the parent cell. These daughter-cysts are of all sizes, from that of a pea to that of a hen's egg. No heads of echinococci could be discovered, but some hooklets were found. The ova of the echinococcus were supposed to enter the human intestines through the agency of drinking water.

Dr. Welch then gave an elaborate demonstration on the blackboard of the development of echinococcus cysts in the human subject. After describing particularly the endogenous and the exogenous, he went on to speak of the third form, the multilocular cyst. This, he said, had never been met with in this country, and as it was found exclusively in Switzerland and Southern Germany, he thought it probable that it was not produced by the same embryo as the others. In the case which he presented, there seemed to be an attempt at spontaneous cure. The explanation of the special condition found was to be looked for in the presence of the very thick fibrous capsule, which had caused a marked narrowing of the bloodvessels passing to the growth, and the parasites were thus, to a great extent, deprived of their means of subsistence. As regards echinococcus cysts in general, they were not frequent in this country. Sixty-one cases had been collected by Osler, of Montreal, and a large number of these were in foreigners. Personally, he had seen four cases in the dead-house of Bellevue Hospital. All these were in foreigners; three of the patients being Germans, and one an Irishman.

It had been a question in his mind whether the affection ever occurred in native Americans; but, on the whole, he was inclined to the opinion that it did in certain rare instances. In this case, the spleen was flattened out to three times its natural length. The fluid which the cyst contained was clear, opalescent, and having only a trace of albumen in it. The negative character

of the fluid was the main point of diagnosis in these cysts during life; but it was always to be borne in mind that the fluid of parovarian tumors (cysts of the broad ligament) was almost exactly similar. It was difficult to make the diagnosis with certainty, therefore, unless hooklets were discovered, when, of course, there could be no longer any doubt about the matter.

At the conclusion of Dr. Welch's remarks, the Society went into executive session.

MEDICO-CHIRURGICAL SOCIETY OF MONTREAL.

Stated Meeting, December 14, 1883.

THE PRESIDENT, T. A. RODGER, M.D., IN THE CHAIR.

TERTIARY SYPHILIS: CEREBRAL, LARYNGEAL, AND RECTAL.

DR. GEORGE ROSS presented the specimens, accompanied by the following history: Woman, aged thirty-six, was brought to hospital November 20th, with left hemiplegia; eyes fixed, and deviating to the right; pupils contracted; eyeballs prominent; both upper eyelids drooped slightly; tongue protruded to left side. Roused with difficulty, and then answers questions rationally in a whispered voice. Paralysis not complete in left side; she could lift the leg a little, and offered slight resistance to flexion and extension of the arms. Complained of pain in the right occipital region. No fever. Patient had been under treatment for necrosis of palate, and syphilitic affection of eyes and larynx. Had severe headaches all summer. The present attack began four days before admission. On the evening of the 10th, she went to bed in usual health, but during the night she behaved strangely and did not seem well. The next day her husband noticed that there was something wrong with the left arm, as she did not use it freely. On Sunday, the 19th, there was hemiplegia. While in hospital, no change took place in the paralyzed parts. The right cornea became turbid, and an ulcer formed; there were the other evidences of involvement of the right fifth nerve. There was right external strabismus. Passed a good deal of pus and mucus from the bowel, and on digital examination a firm stricture was felt about one inch and a half from the anus. The breath was fetid, and towards the close there was considerable laryngeal stridor. There was great tenderness of the larynx externally. She gradually sank, and died on the 8th. The corneal ulcer healed, but the tissue remained opaque.

The brain presented extensive syphilitic disease at the base and in the right Sylvian fissure. The right temporo-sphenoidal lobe was firmly adherent in the middle fossa, and both dura and pia mater thickened and adherent. The fifth nerve, just as it entered the Gasserian ganglion, was involved in a mass of gummatous tissue, growing beneath, and attached to the margin of the tentorium. The nerve, for a quarter of an inch was swollen, and the fibres separated. The right optic nerve, close to the commissure, was surrounded by recent infiltration, and was inflamed and swollen to nearly double the size of the left nerve. The right sixth appeared involved, but the third was free. The right temporal and orbital convolutions were firmly united together by thickened and infiltrated tissue. The right middle cerebral was small, and a few lines from its origin passed directly into a gummous mass which surrounded it for nearly half an inch. The membranes in the fissure beyond this were free, and the arteries small and full of white and red thrombi. The vessel in the gumma was quite occluded. The anterior cerebral artery contained a tolerably firm clot. The other vessels and the rest of the base looked normal. There was red softening of the convolution and parts supplied by the middle cerebral, particularly of the island and the ascending convolutions. Both nuclei of the corpus striatum were softened. The right optic disk was slightly swollen, but the intense neuritis evident near the commissure did not extend the whole length of the nerve.

There was extensive destruction of hard and soft parts of the palate, and ulceration of upper part of pharynx, and in the nose. The larynx presented advanced syphilitic disease; ulceration of both cords—most of the left. The greater part of the thyroid cartilage was neurotic, broken into three or four segments, and surrounded with sloughing tissue. There was suppuration beneath the sterno-thyroid and thyro-hyoid muscles. The anterior part of cricoid cartilage was also necrosed. The rectum presented a large area of ulceration, and a short distance within the anus there was cicatricial tissue in the form of an annular ring.

DR. HENRY HOWARD remarked on the frequency of cerebral syphilis, and gave his experience of its connection with acute mania and other forms of insanity.

PREATAXIC TABES DORSALIS.

DR. JAMES STEWART presented a patient whose history and symptoms were as follows: James C., aged 33, clerk, complained only of dimness of vision. He first noticed it ten weeks ago, and three weeks after consulted Dr. Butler, who diagnosed the case as one of tabes. Twelve years ago he had double vision for a week. In the year 1879, he also recollects seeing double for three days. His general health has been excellent. Has never had syphilis. Three years ago he worked for several months in a very damp cellar. Family history is unimportant. *Present state:* There is permanent contraction of the right pupil (paralytic myosis). There is loss of reflex contraction of the pupils, while both contract on accommodation. There is also loss of reflex dilatation of the pupils; when the skin is ever so severely irritated by the faradic brush, there is no response. There is well-marked atrophy of both disks. The patellar reflex is absent in both legs, and this with the eye phenomena are the only symptoms of tabes present. No lightning pains, no bladder or rectum pareses, no ataxia, no delayed, lost, or perverted sensations. The skin reflexes are present. Notwithstanding the absence of so many prominent symptoms, there can be no doubt that the case is one of tabes dorsalis in the preataxic stage. The case is a good illustration of the now generally conceded opinion that the disease is essentially one of the sensory tracts. Three of the prominent symptoms are failure of normal reflexes. 1. Reflx contraction of the pupils. 2. Loss of the reflex dilatation. 3. Loss of the patellar reflex. The patient has been treated during the past seven weeks with the faradic brush, three times weekly, after the manner recommended so highly by Rumpf of Borne.

DR. R. PALMER HOWARD spoke of the importance of these early eye symptoms in tabes, particularly myosis and irregularity of the pupils, and narrated several cases in illustration. Myosis, in his experience, was associated chiefly with two affections, tabes and progressive paresis. The great rapidity of the pulse in some instances had attracted his attention. In three cases under observation, it was always about 100, and he had met with one with a pulse of 140. With regard to the use of the faradic brush, he had a patient at present under this treatment in whom the anæsthesia had been greatly relieved by its use.

DR. HENRY HOWARD spoke of impotence as an early symptom of locomotor ataxia, and asked if this patient still retained his sexual vigor.

DR. OSLER asked if the double vision twelve years ago could be attributed to the same cause as the eye symptoms now present. In cases associated with syphilis the early ocular troubles may be sometimes due to it, as in a patient of his, who had double vision and other symptoms of cerebral syphilis years before the tabes developed.

DR. BULLER remarked that this patient consulted him on account of failing vision, and he found his sight much impaired, R. E. V. = $\frac{20}{C}$; L. E. = $\frac{20}{LXX}$; with great concentric limitation of the visual field. The field for colors was contracted in a similar manner, but there was no central scotoma. The optic nerves presented the usual appearance of progressive atrophy of spinal sclerosis. The condition of the eyes, together with the absence of patellar reflex, seemed to warrant the diagnosis of locomotor ataxia. With regard to the atrophy of the nerves in this disease, Dr. Gowers has made the observation that when this condition comes on early in the course, in the first or preataxic stage, the resulting loss of vision is more rapid, and more complete, than when occurring as a later symptom. This coincided with his experience. When atrophy of the nerves occurred early, it was often, he thought, a matter of doubt whether the trouble was of spinal origin. He knew of several cases in which optic atrophy had led to complete blindness, now lasting for one, two, or three years, without the development of fresh spinal symptoms, although there had been all along absence of the patellar reflex. All of these cases had been regarded as commencing locomotor ataxia by the very highest authorities, both in Europe and America.

DR. STEWART, in reply, said that, so far as the patient knew, he was not impotent.

TAIT'S OPERATION.

DR. ARMSTRONG exhibited a pair of diseased ovaries which he had removed from a single woman, aged 22, who had suffered for three years with pelvic pain, and, for the past year, menstruation every fortnight, not profuse, but accompanied by severe pain. The loss of appetite and vomiting at each period had so reduced her strength that she was quite unfit for work. The ovaries were felt to be enlarged and prolapsed. She was not hysterical. The ovaries were enlarged to the size of walnuts, thickened and fibroid; no adhesions. The patient had done well since the operation, which it was hoped would permanently relieve her.

FIBRO-GLIOMA OF UPPER END OF ASCENDING FRONTAL GYRUS; JACKSONIAN EPILEPSY OF FOURTEEN YEARS' STANDING; THE LEG-CENTRE.

DR. OSLER read a report of the case, and presented specimens and drawings in illustration. The case occurred in the family of a medical man, and was remarkable from the length of time during which the convulsions had lasted, and the limitation of the lesions. After preliminary remarks on cortical epilepsy and the value of pathological cases in localizing the functions of the brain, the notes furnished by the Doctor were read, of which the following is an abstract: "Mary ——, aged fifteen years and nine months. When sixteen months old fell on her head from the table and appeared to be much hurt, but recovered without any serious effects. Five months after, the left hand was noticed at times to be stiff and firmly closed. This continued to increase in severity and frequency for three months, when the leg became similarly affected, and two months later she was confined to bed, as the paroxysms had become general. For eight or ten weeks the seizure continued in this violent way; sometimes she had eight or ten in an hour. No loss of consciousness; then, after lasting for about seven months, they ceased, and she ran about apparently quite well.

She remained free from spasms for a year, when they returned and ran much the same course for six or seven months, and she then again recovered for about the same length of time. This went on until her eleventh year; months in which the spasms were severe and months in which she was quite free. One of the attacks is described by the Doctor as follows: "suppose her at the dinner table. She would suddenly say, 'Oh! I am going to have a spasm' (she knew this by the contraction of the left hand), she would then jump up and go to the sofa, get a cushion, lay it down on the floor, then lie down with her head on the pillow, and then jerk away in a spasm for half a minute or a minute; laughing or talking all through it, and never losing consciousness. She would then get up, replace the cushion, and come back to the table and finish her dinner." About six years after the illness began, the left leg began to show signs of weakness, and gradually the foot turned in. During her eleventh, twelfth, thirteenth, and fourteenth years, the seizures were very bad, and she had no prolonged intervals. For six weeks, at one time, she lay unconscious, and had from fifty to eighty spasms in the twenty-four hours. As the attacks became less frequent she was able to sit up in bed or in an easy chair, and read or do fancy work. Last Christmas, when she was fifteen years of age, the spasms suddenly ceased, and she was ten months without one. A week before her death they returned with great violence, and increasing frequency until they became almost continuous, and for two days there was coma. Three hours before death they ceased, and she passed away quietly. The left arm and hand were weak, not wasted; the left foot was flexed inwards at right angles, and firmly fixed in that position. In reply to questions, the Doctor gave some additional particulars. The spasms always began in the left hand, and appeared to extend to the leg first, and then to the face. The intellect was clear, and she was, though without special instruction, beyond her years in intelligence and general information. The clinical history may be briefly given as follows: Cortical epilepsy

for fourteen years; remarkable intermissions of from six to twelve months. Spasms began in the left hand, at first monobrachial, then extended to the leg, afterwards became unilateral, and finally general. No loss of consciousness for some years. Weakness of left arm, permanent contracture of right leg and foot. Intellect unaffected.

The brain was large and well formed, dura mater natural, no adhesions or spots of thickening on the pia mater, vessels much congested, hemispheres symmetrical, no wasting of convolutions or puckering. In slicing the organ *pre-frontal* and *pediculo-frontal* sections normal. A section three centimetres in front of the fissure of Rolando showed nothing abnormal. In making the *frontal* section, the knife passed through a hard resistant mass in the right hemisphere, occupying the upper end of the ascending frontal convolution. The knife passed exactly two centimetres in front of the fissure of Rolando and the mass occupied the superior fasciculas of the white fibres, nowhere reaching the surface and scarcely touching the gray matter. In this exposure it measured fourteen millimetres in width by sixteen in vertical extent, and was eight millimetres from the surface of the paracentral lobule, ten millimetres from the top of the gyrus close to the longitudinal fissure, and fifteen millimetres from the external surface of the convolution. In a section seven or eight millimetres behind the *frontal* the mass was visible as a small round puckered portion just at the edge of the gray matter, at the bottom of a small sulcus passing into the ascending frontal gyrus from the fissure of Rolando. The mass occupied the upper end of the convolution, and had an antero-posterior extent of about seventeen millimetres, and a vertical of fifteen or sixteen millimetres. It was almost entirely within the white matter, but touched upon the gray at several spots. It had a fibrous appearance with ill-defined borders; and vessels could be seen in it. The *parietal* and other sections were normal. The right crus was badly torn, and no sclerosis could be seen, but the right half of the medulla was smaller than the left and presented evidence of descending degeneration. The cord was not examined.

Histologically the mass appears to be a fibro-glioma. The delicate fibre elements are in excess, but there are many large cells with prolonged fibrillar process. The bloodvessels are numerous. So far as examined, the cells of the gray matter in the immediate vicinity did not appear to be much altered.

Dr. Osler remarked that lesions causing cortical epilepsy were rare in the white matter, but this one was close enough to the gray cortex to induce the irritative effects and the excessive motor discharges causing the convulsions. Gliomata were slow-growing local tumors, and instances were on record of nearly as long duration as in the case under consideration. Dr. Jackson had described one of ten and another of twelve years' standing. The remarkable intermissions were strange features in these cases; periods of quiescence alternating with periods of excessive irritation. The situation of these lesions was of interest in connection with the crural monoplegia and contraction. The tumor occupied largely the anterior portion of the paracentral lobule, the region which has been found affected in the few recorded instances of paralysis of one lower extremity of cerebral origin. The leg-centre is placed in this lobule by Ferrier and Charcot, and this case is in confirmation, as we may reasonably conclude that the lesion, by interfering with conduction from this centre, induced the paralysis and subsequent contracture.

DR. HENRY HOWARD made some remarks on the cases of epileptiform convulsions which he had seen.

DR. HAMMETT HILL, of Ottawa, narrated the case of a lumberman, who was struck on the head with a pike, and received a depressed fracture. He had severe seizures, and was trephined with success, and he had no fits for eighteen years, after which they recurred at long intervals, possibly due to bony thickening about the seat of trephining.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 19, 1883.

THE PRESIDENT, WM. M. WELCH, M.D., IN THE CHAIR.

DR. ROBERTS BARTHOLOW read the following paper on

NITROGLYCERINE AND THE CHLORIDE OF GOLD AND SODIUM IN THE TREATMENT OF ALBUMINURIA.

Hitherto the therapeutics of renal diseases have not advanced in the same ratio as our knowledge of their pathology. It cannot be said now that a cure has been found, but that two remedies of real value are available. I shall attempt to define the place which these remedies should occupy in a curative scheme. To do this, in even the briefest way, I must clear the ground with a preliminary statement.

I start with the proposition that those renal lesions united by the common symptom—albuminuria—are of neural origin. There is a kinship between diabetes and Bright's disease. One of these is sometimes substituted for the other; and during the course of some rare cases of exophthalmic goitre this substitution occurs. Irritation of a certain part of the floor of the fourth ventricle is followed by glycosuria; of another part by albuminuria. The recent observations of Da Costa and Longstreth prove that a relation exists, whether causal or sequential, between certain renal lesions and degenerative changes in some ganglia of the abdominal sympathetic. The hypertrophy of the muscular coat of the arterioles, discovered by Dr. George Johnson, and the increased tension of the vascular system due to an irritation of the vaso-motor centre in the medulla, both present in the chronic forms of albuminuria, are further evidences of the agency of the nervous system. It was, more especially, the condition of elevated tension of the vessels which led to the use of nitroglycerine. This remedy before all else reduces the vascular tension. It also lessens the work of the heart by removing the inhibition exercised by the pneumogastric nerve.

This remedy appears to have been first used by Mr. Robson, an English surgeon, in cases of albuminuria, and by him employed, because the high tension of the vascular system has proved to be so pronounced an element in the more chronic cases. I have, myself, seen some remarkable instances of relief—indeed of cure—effected by it. In cases of mitral disease accompanied by albuminuria, it also renders the highest service—for the diminished peripheral tension lessens the work to be done by the heart, and assists in the more equal distri-

bution of the blood. The effect of this in relieving the renal congestion is obvious.

Chloride of gold and sodium has quite another function. It has long been known that this remedy has a special direction to the genito-urinary apparatus. The ovarian and uterine organs in the female, the testes and vesiculæ seminales in the male, are stimulated by it, and the kidneys, by means of which it is eliminated, and in which it tends to accumulate, are decidedly affected by it in function and structure. In common with some other agents of the class to which gold belongs—for example, corrosive sublimate—the chloride acts on connective tissue, and checks its over-production, or its hyperplasia. It would be quite impossible in this note to go over the evidence on these points, and hence I must ask assent to these statements. They have been accepted as true of gold, from the days of the alchemists and iatrochemists, as any one may ascertain from that curious collection of mediæval medical learning—the Anatomy of Melancholy. It has happened, strangely enough, that Hahnemann and his followers have profited by this knowledge, and have used gold preparations, especially *aurum potabile*, in the treatment of renal diseases with success.

How and when are these remedies to be used?

Nitroglycerine is now administered, as all present know, in the form of the centesimal solution—1 minim of the pure drug to 100 minims of alcohol. The initial dose of this one per cent. solution is one minim, which should be increased until the very characteristic physiological effects are produced. The susceptibility to the action of nitroglycerine varies greatly, and hence the dose cannot be stated in advance. It is necessary to produce some obvious effect. To maintain the same level of action, a slight increase in the dose may be required from time to time. As the effect is not lasting, the interval between the doses should no exceed three or four hours.

The administration of nitroglycerine should begin in acute cases immediately after the subsidence of the acute symptoms. It is indicated in chronic cases at all periods, but is more especially useful if given before hypertrophy of the muscular layer of the arterioles has taken place. When it acts favorably, the amount of albumen in the urine steadily diminishes. The mechanism of its action consists in the lowering of the pressure in the renal vessels. How far any curative effect proceeds from action of this remedy on the sympathetic system remains to be determined.

Cloride of gold and sodium is indicated in the subacute and chronic cases, especially the latter. The earlier it is given, the better, if structural changes are to be prevented or arrested. The good effects to be expected from it will depend necessarily on the extent of the damage already inflicted on the kidneys.

The usual dose is $\frac{1}{20}$ grain twice a day, but this may be much increased, if necessary. At the outset, $\frac{1}{10}$ grain may be given; in a week, the dose should be lowered to $\frac{1}{15}$ grain, and after a month the regular dose of $\frac{1}{20}$ grain should be steadily pursued, with occasional intermissions. Indigestion, gastralgia and colic pains, nausea, or diarrhœa are occasionally caused by it; and, if so, the quantity administered must be reduced. It is usually borne without any discomfort, but after prolonged administration, salivation, weakness, emaciation, trembling, and other nervous phenomena may occur possibly. Such effects, however, are wanting in my experience.

The treatment of albuminuria by nitroglycerine and the chloride of gold and sodium does not necessitate the exclusion of other means—hygienic, climatic, or dietetic. These remedies should, however, be given uncombined, at different hours, and their actions should not be hindered or obscured by the effects of other agents given with like purpose. To this general statement there may be two exceptions: with nitroglycerine, amyl nitrite or sodium nitrite may be given; with the gold and sodium chloride, corrosive sublimate may be combined. If doubts may be felt in regard to the propriety of depending on the utility of these remedies, they need not be long experienced, for if no good effects are observed in two weeks, they may then be discontinued.

DR. CHARLES H. BURNETT then read a paper on

THE SUPPOSED CONNECTION BETWEEN EAR DISEASE AND KIDNEY DISEASE.

Early writers on disease, he said, have shown a knowledge of the fact that alterations in hearing occur in the course of general diseases, as, for example, in diseases of the kidneys. It was supposed by them that the alteration in the functions of the ear, in this form of disease, was due to changes in the auditory nerve. But the results of the more reliable modern investigations tend to show that if an ear disease be due to kidney disease, the lesion usually occurs in the tympanic cavity, and not in the auditory nerve.

Certainly accidents of a hemorrhagic or apoplectiform nature might be expected either in the tympanic cavity or internal ear, in Bright's disease, when we reflect upon the deterioration of the blood and upon the malnutrition and friability of the vascular system, in the later stages of the malady. Further, as Bright's disease is characterized by a tendency to inflammation, especially in serous membranes, and as the membranous structures of the internal ear, or labyrinth, belong to this class of membranes, very naturally organic changes in these tissues might be looked for in Bright's disease of the kidneys.

However, as late as 1856, Rau, in his *Ohrenheilkunde*, published in Berlin in that year, claimed that there was not a solitary reliable observation at that time on record in favor of any symptomatic relation between the ear and the urinary organs. In 1869, Schwartze[1] reported a case of extravasation of blood into the tympanum, as peculiar to Bright's disease, though of rare occurrence; and in the same year, Dr. G. M. Smith, of New York,[2] called attention to the fact that impairment of hearing was at times one of the symptoms of Bright's disease, and a symptom which could not be explained by referring it to uræmia. In 1873, Dr. Roosa, of New York, in his treatise on the ear, referred to an obstinate case of suppuration and pain in the middle ear in a man sixty-one years old, suffering from Bright's disease. In this case, it was supposed that the effect of the renal disease upon the tympanic vessels was the cause of the acute suppuration, and it was also supposed that the disease in the

[1] Archiv f. Ohrenheilkunde, Bd. iv. S. 12.

[2] N. Y. Acad. of Med. See Roosa's Treatise, 1873, p. 257.

drum-cavity was originally hemorrhagic in nature. The subject was deemed of enough importance to place a physician on his guard for renal disease in cases of hemorrhage into the tympanic cavity. It must not be forgotten, however, that there is a purely sthenic form—otitis media hemorrhagica, occurring in subjects entirely free from kidney disease, in which the only effusion is pure blood, the removal of which from the tympanum by paracentesis is followed by cessation of pain and return of hearing.[1]

Again, in 1878, Schwartze[2] states that serous catarrh of the tympanic cavity is found in syphilis, heart disease, pneumonia, Bright's disease, naso-pharyngeal catarrh, and apparently may be due sometimes to vaso-motor disturbances. The same author says, hemorrhages into the labyrinthine cavity and the membranous labyrinth occur in kidney diseases. Also, that extravasations of blood into the tympanum occur spontaneously with acute inflammations in morbus Brightii, cynanche diphtheritica, and in endocarditis verrucosa recens et ulcerosa.

Dr. Paul Pissot,[3] in an inaugural thesis, is disposed to consider three forms of aural disease, which may arise in Bright's disease, viz., tinnitus aurium, partial deafness, and complete deafness. His conclusions are, that affections of the hearing may arise at the beginning or during the course of the renal disease. Intermittence seems to be characteristic of these forms of deafness, which may be contemporaneous with the œdema, or may precede it. They appear with all forms of the disease, and are manifested with variable intensity. But he cannot say to what special lesion of the ear, or of the nerve of hearing, their symptoms are attributable. Delacharrière, a responsible aurist, examined the cases upon the history of which the thesis is based, and found rupture of the membrana tympani, abnormal vascularity of the manubrium, and sclerosis of the tympanum, and was disposed to regard the conditions as causative forces. Pissot held that the hypothesis of Rosenstein, according to which there is œdema in the course of the auditory nerve within the cranium, may explain the intermittence and variations of intensity in these morbid manifestations. This latter process may be analogous to the œdema of the glottis and vocal cords noted in Bright's disease by Fauvel, in 1864. A similar symptom has been noted by Sée.

In alluding to chronic, non-suppurative aural catarrh in children, Von Troeltsch[4] says: "A greater blood pressure from increased action of the heart, as in Bright's disease, must necessarily produce a certain hyperæmia, even in the mucous membranes of the head." Albert H. Buck,[5] of New York, expresses the opinion that in some instances a serous fluid, deeply tinged with the coloring matter of the blood, finds its way into the tympanic cavity through other than inflammatory causes.

[5] Diagnosis and Treatment of Diseases of the Ear, N. Y., 1880, p. 164.

"Instances of the latter form of disease are very rarely met with, and then usually in connection with a depraved state of the general nutrition, as in morbus Brightii."

Dr. Maurice Raynaud[1] expresses the opinion that diabetic otitis is not only more frequent than is supposed, but that when this has once become a well-known fact, it may prove a pathognomonic index, like anthrax, diffuse phlegmon, and certain erythematous eruptions about the genitals, and arouse suspicion of the presence of the renal disease hitherto unsuspected. He cites a case of well-marked diabetes mellitus, in which there suddenly occurred one evening, a severe earache, after the patient had been in the hospital two weeks, and most carefully watched, so that no chilling could have been the cause of the ear pain. The pain became intense, and towards midnight of the same evening in which the pain set in, there occurred an abundant hemorrhage from the drum-cavity of the affected ear, which was followed by immediate relief. This was followed for several days by a copious sero-sanguinolent, and then serous discharge, which contained leucocytes, and albumen, as shown by heat, but no sugar. Post-mortem examination, twenty-three days after the attack of otitis, revealed a large perforation in the anterior segment of the membrana tympani; red, fungous, and bleeding mucous membrane in the drum-cavity, in which there was a pink, purulent liquid. The ossicles were not dislocated, but were imbedded in granulations, and near the stirrup was a clot of blood. The mastoid cavity was filled with a rose-colored liquid, containing pus-cells, and its bone substance was greatly injected and marbled, presenting all the appearances of inflammation of bone tissue. The labyrinth showed no alterations. The author concludes that osteitis in the petrous bone is a peculiar and constant symptom of diabetic otitis.

P. McBride,[2] in an article devoted to the consideration of the various causes leading to aural disease, states that "occasionally the ear is affected in Bright's disease by hemorrhage into the tympanic cavity. The tympanum becomes filled with blood, which probably either becomes absorbed or leads to suppuration. Schwartze was perhaps the first to observe this condition." McBride further says: "I am not aware that sudden labyrinthine deafness in the course of Bright's disease has been described, but it seems probable that such a contingency might be looked for here and also in pernicious anæmia, in which retinitis hemorrhagica is not uncommon." In the recently published work of Prof. Politzer,[3] on the ear, the author's experience is that in cases in which a supposed connection existed between the organic renal disease and an aural malady, the fundamental cause lay in very apparent changes in the middle ear. He has also found that "catarrhs of the ear run an unfavorable course in tuberculosis, Bright's disease, and all cachexiæ by which the nutrition of the general system has become deteriorated."

Dr. Burnett then offered the following

CONCLUSIONS.

1. Evidences in favor of either frequent or well-marked aural lesions, dependent upon renal diseases, are extremely meagre.

[1] Clinical lecture at La Charité, Paris. Annales des Maladies de l'Oreille, etc., March, 1881.

[2] Edin. Med. Journal, February and March, 1882.

[3] Cassell's English Translation, 1883, Phila.

2. Those lesions in the ear, which have been found in connection with Bright's disease and diabetes mellitus, and which may have been dependent upon the dyscrasia induced by these renal disorders, are in the form of sero-sanguinolent and hemorrhagic effusions into the drum-cavity. But the latter must not be mistaken for the sthenic form of otitis media hemorrhagica.

3. From the serous nature of the membranous structures of the labyrinth, organic changes might reasonably be expected in Bright's disease, but positive proof of the occurrence of such lesions based on ante- and post-mortem history is wanting.

NEWS ITEMS.

MEDICAL MATTERS IN CONGRESS.—The following bills, of medical interest, have been introduced in Congress during the past week:

H. R. 2697, introduced by Mr. Randall, of Pennsylvania, to prepare and publish a National Pharmacopœia for the United States, which was read a first and second time, referred to the Committee on Ways and Means, and ordered to be printed.

H. R. 2785, introduced by Mr. Young, of Tennessee, to amend an Act entitled "An Act to prevent the introduction of infectious and contagious diseases into the United States, and to establish a National Board of Health," which was read a first and second time, referred to the Committee on the Public Health, and ordered to be printed.

S. 982, introduced by Senator Miller, of New York, for the maintenance and support of the Marine-Hospital Service. Read twice by title, referred to the Committee on Commerce, and ordered to be printed.

THE YELLOW FEVER OF 1883 AT PENSACOLA.—The total number of cases of yellow fever, and mortality, at Pensacola Navy Yard and adjacent villages, in 1883, is given as follows: Pensacola Navy Yard, cases, fifteen; deaths, six. Woolsey and Warrenton, cases, one hundred and fifty-two; deaths, twenty-seven. Total, one hundred and sixty-seven cases; thirty-three deaths.

HEALTH OF HAVANA.—Sanitary Inspector Burgess, U. S. Marine-Hospital Service, reports that there were five hundred and seventy-eight deaths from all causes at Havana, Cuba, during the month of December, 1883; of which fifty-three were from yellow fever, eleven from typhoid fever, thirteen from malarial fever, four from diphtheria, four from croup, and one from glanders. Forty-three of the deaths from yellow fever were among citizens and the merchant marine, and the remaining ten among the army and navy. During the week ending January 4, 1884, there were seven fatal cases of yellow fever. During the month of December, 1882, there were five hundred and thirty-five deaths, only twenty-four of them being from yellow fever; and during the week ending January 4, 1883, but four from that disease.

CONSULAR REPORTS CONCERNING YELLOW FEVER.—Yellow fever appeared on board the mail steamer "Lima" bound from Panama to Callao. The U. S. Consul, under date of December 12, 1883, reports that the disease appeared when two days out, and three persons died from the disease. The steamer was placed in strict quarantine, and no fresh cases were reported. The U. S. Consul says: "Every possible precaution is being observed on shore to avert contagion, but from the circumstance of the advent of our heated term, much anxiety is manifested."

The U. S. Consul at Buenos Ayres states that two cases of yellow fever were landed at that place from a French steamer which touched at Rio Janeiro, and that the apprehensions caused thereby induced the authorities at Montevideo to place a ten days quarantine on all vessels proceeding from Buenos Ayres. There is a quarantine of three days observed by Buenos Ayres of all vessels from Brazilian ports.

INTERNATIONAL MEDICAL CONGRESS.—The Secretary of State is in receipt of a communication from the Danish Minister, in Washington, D. C., relative to the Eighth Annual Session of the International Medical Congress, which is to be held in Copenhagen in August next. The following is a copy of the letter:

"I am officially informed by my government that the Eighth International Congress for Medical Science, will meet at Copenhagen in the days from the 10th to the 16th of August, 1884.

"The different States having generally been represented, at the preceding meetings of this Congress, by different official delegates, His Danish Majesty's Government entertains the hope that this may also be the case at the impending Congress. Conforming to the wish expressed by the Board of Organization, I am instructed to assure the Government of the United States that the Danish Government would highly appreciate the fact of its being officially represented at the Congress, and to invite you to inform me, in good time, of the names of the delegates to whom may be intrusted this distinguished mission. I have the honor to inclose five copies of the letter of invitation issued by the Committee of Organization, to which will be added later the definitive programme of the labors of the Congress.

"Reminding you that the Eighth International Congress (according to the notice already published some months ago in the medical journals) will be held in Copenhagen from the 10th to the 16th of August, 1884, we have the honor of communicating to you that the General Organizing Committee, formed for the preparatory work, is composed of the following members, living either in or near Copenhagen:

"President, Professor Dr. P. L. Panum. Secretary General, Professor C. Lange. Secretaries, Dr. O. Bloch, Dr. C. J. Salomonsen, and Surgeon-General Joh. Maller. Honorary Treasurer, Professor Dr. E. Hansen Grut. Also the Presidents of the Special Committees of the Section of Anatomy, Professor Chievitz; of the Section of Physiology, Professor Dr. P. L. Panum; of the Section of General Pathology and Pathological Anatomy, Professor Dr. C. Reisz; of the Section of Medicine, Professor Dr. F. Trier; of the Section of Surgery, Professor Dr. Holmer; of the Section of Hygiene and State Medicine, Dr. E. Hornemann; of the Section of Military Surgery and Medicine, Director-General of the Medical Department of the Army, Salomon; of the Section of Mental and Nervous Diseases, Professor Dr. Steenberg; of the Section of Obstetric Medicine and Surgery Gynecology, Professor Dr. Stadfeldt and Professor Dr. Horvitz; of

the Section of Diseases of Children, Professor Dr. Hirschsprung; of the Section of Ophthalmology, Professor Dr. E. Hansen Grut; of the Section of Diseases of the Skin and Syphilis, Professor Dr. Haslund; of the Section of Diseases of the Ear, Dr. W. Meyer; of the Section of Diseases of the Throat, Dr. W. Meyer.

"The Special Committees formed for the aforesaid Sections have, when they found it useful, completed their number by members living outside Copenhagen, partly in Denmark, partly in the other Scandinavian countries.

"In order that the meeting of so many distinguished medical men, whom we hope to see on this occasion, may be as advantageous as possible, the Organizing Committee, following the example of the later Congresses, will communicate with distinguished men of different branches and of different countries, in order to prepare a programme. This programme, as well as the rules, will be forwarded to those of our colleagues whom we suppose take an interest in the work of the Congress, and who might be inclined to participate in it."

INTERNATIONAL CONGRESS OF HYGIENE.—A note from the Minister of the Netherlands in Washington, received by the Secretary of State, gives the information that the International Congress of Hygiene will hold its next session at the Hague, beginning August 21, 1884, and that "Governments, States, Corporations, etc., are invited to send delegates."

NEW YORK STATE MEDICAL SOCIETY.—The Seventy-eighth Annual Meeting of the New York State Medical Society will be held on Tuesday, February 5th, under the presidency of Alexander Hutchings, M.D. The following papers are announced to be read:

Malignant Lymph-Adenoma, with Cases, by Dr. L. S. Pilcher, Brooklyn. Dysmenorrhœa; its Treatment by Dilatation, by Dr. W. W. Potter, Buffalo. Operation for Closure of the Hard and Soft Palate, with Results, by Dr. A. Vanderveer, Albany. Value of Electricity in Diagnosis, by Dr. L. E. Felton, Potsdam. The Treatment of Suppurative Otitis in Children, by Dr. S. Sexton, New York City. A Case of Sympathetic Serous Iritis, with Remarks, by Dr. D. Webster, New York City. Strangulated Hernia, with Reports of Five Cases Treated by Operation, by Dr. J. Chapman, Medina. Two Unusual Cases in Obstetrical Practice, by Dr. W. C. Wey, Elmira. A New Method of Partial Extirpation of the Cancerous Uterus, by Dr. E. Van de Warker, Syracuse. Two Cases of Poisoning by Tansy, by Dr. W. Woodward, Big Flats. Hæmaturia; Two Cases of Extra-Uterine Pregnancy; and Two Cases of Rupture of the Heart, by Dr. T. H. Squire, Elmira. Management of Face Presentation, by Dr. E. L. Partridge, New York City. Morbid Somnolence, by Dr. C. L. Dana, New York City. An Operation for Correcting Deformity of the Auricle, by Dr. O. D. Pomeroy, New York City. Rheumatic Joint Lesions of Children, by Dr. V. P. Gibney, New York City. Biographical Sketch of the Late Dr. G. W. Bradford, by Dr. C. Green, Homer. Orbital Cellulitis, by Dr. T. R. Pooley, New York City. Biographical Sketch of the late Dr. J. F. Jenkins, by Dr. G. J. Fisher, Sing Sing. Poisoning by Potassium Chlorate, by G. B. Fowler, New York City. Spontaneous Pyæmia, by Dr. J. B. Todd, Parish. The Establishment of Hospitals in Small Cities, by Dr. E. H. Parker, Poughkeepsie. House Sanitation; as it is and as it should be, by Dr. W. F. Sheehan, Rochester. Croup as distinguished from Diphtheria, by Dr. A. G. Crittendon, Clifton Springs. The Medical Society of the State of New York in its Relation to Sanitary Science and the Public Health, by Dr. E. Harris, Albany. A Plea for the Pharmacopœia, by Dr. L. Johnson, New York City. Canalization, as Applied to Amputation of the Female Breast, to insure Primary Union under one Dressing, by Dr. A. G. Gerster, New York City.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.—The annual meeting of this Society will be held at Philadelphia on May 14, 15, and 16, 1884, in the Assembly Room of the Union League, Broad and Walnut Streets. The President's reception and the entertainment by the Philadelphia County Medical Society will be held on the evening of May 14, at the Pennsylvania Academy of the Fine Arts, Broad and Arch Streets.

Notice is given that all those who wish to present papers should send the full title and a short abstract of the same to the Committee on Arrangements, John B. Roberts, Chairman, 1118 Arch Street, Philadelphia, on or before March 1, 1884.

THE MISSOURI STATE BOARD OF HEALTH, at a meeting on January 9th, unanimously adopted resolutions concerning the recognition of the diplomas of certain medical colleges.

Resolved, That it is expedient to recognize the Joplin College of Physicians and Surgeons; that it does not recognize the St. Louis Eclectic College; and that it does not recognize as in good standing the Kansas City Hospital College of Medicine, and the American Eclectic College of Cincinnati.

Six applicants presented themselves to the Board for personal examination as physicians, of whom three were accepted and three rejected. In a number of cases of applications for certificates, information had been presented to the Board charging the applicants with an unprofessional mode of practice. A number were rejected on this ground. In others, where the evidence was not conclusive, certificates were ordered issued. It is stated that some of the Colleges not recognized by the Board intend to test the matter in the courts.

THE NEW YORK OPHTHALMOLOGICAL SOCIETY.—At the Nineteenth Annual Meeting of the New York Ophthalmological Society, held last Monday evening, the following officers were elected for the ensuing year:

President.—David Webster, M.D.

Vice-President.—C. J. Kipp, M.D., of Newark, N. J.

Secretary and Treasurer.—James L. Minor, M.D.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL is preparing to increase further its field of usefulness in the way of medical teaching by making an effort towards combining the school with a hospital of its own. On or about February 1, 1884, it will enter its new quarters in East Twentieth Street, between Second and Third Avenues, where the accommodations will be most ample for its school and for sixty to one hundred patients. One hundred and forty practitioners of medicine matriculated at the school during the year that ended

November 1, 1883. Over sixteen thousand patients were rendered available for the purposes of clinical instruction.

THE PHILADELPHIA POLYCLINIC.—The Annual Report of the Philadelphia Polyclinic states that 3301 new patients have been treated in the dispensary between the time of its opening in March and the close of the year 1883; and that this material has been utilized in the clinical instruction in the various specialties of seventy-two pupil physicians.

THE ARCHIVES OF MEDICINE.—G. P. Putnam's Sons take much pleasure in announcing to the subscribers to *The Archives of Medicine* and the profession generally, that DR. E. C. SEGUIN, having resumed his professional work in New York, has been induced to retain the editorial management of the *Archives*. The publication of the *Archives* will, therefore, instead of being brought to a close, as was first announced, be duly continued on the same general plan as that followed during the past six years.

MONUMENT TO DR. SIMS.—Dr. S. D. Gross urges that a monument be erected in the city of New York to the late Dr. J. Marion Sims, and offers to contribute $100 as soon as a committee shall be formed for the purpose of collecting subscriptions.

LEGACY TO THE FRENCH ASSOCIATION.—M. GIRARD has recently left about one hundred thousand francs to the Association Française pour l'Avancement des Sciences. The interest on this sum will be allowed to accumulate for five years, after which it is to be used for the encouragement of persons making contributions to the question of the antiquity of man. The rewards will be given under the forms which the Association may deem proper.

EGYPTIAN OPHTHALMIA IN HUNGARY.—A very severe epidemic of Egyptian ophthalmia has recently broken out in Hungary. Some villages have as many as six hundred affected at one time, and, in spite of every effort by the government and the physicians, the disease seems to be on the increase.

STATISTICS OF FRENCH MEDICAL PRACTITIONERS.—*Le Progrès Médicale* of December 1st furnishes the following analysis of the quinquennial report which the Minister of Commerce has just published:

	1876	1881
Doctors of Medicine,	10,743	11,643
Officiers de Santé,	3,633	3,203
Pharmaciens,	6,232	6,443
Herbalists,	983	982
Midwives,	12,847	13,403

The number of communes in France is 36,097; in these 3645 doctors alone practise; in 1914, Officiers de Santé alone practise; in 743 both Doctors and Officiers de Santé practise, while in 29,795 there are neither doctors nor officers.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending January 5, 1884, indicate that neuralgia and dysentery have increased, and that inflammation of the kidney, tonsillitis, intermittent fever, and typho-malarial fever have decreased in area of prevalence.

Compared with the average for the month of December in the preceding six years, diphtheria, remittent fever, pneumonia, consumption, and typho-malarial fever were less prevalent in December, 1883.

Including reports by regular observers and others, diphtheria was reported present during the week ending January 5, and since, at fourteen places, scarlet fever at nine places, measles at two places, and smallpox in Orleans Township.

OBITUARY RECORD.—HENRY AUGUSTUS DU BOIS, M.D., died of paralysis, in New Haven, Conn., on January 13th, at the age of seventy-three years. He was the sixth lineal descendant of Jacques Du Bois, a French Huguenot, who came to Ulster County, New York, in 1675. He received his Arts degree from Columbia College, New York, in 1827, and the degree of M.D. from the College of Physicians and Surgeons, in 1830. The degree of LL.D. was conferred upon him by Yale College, in 1864; and in the same year he was elected a member of the Academy of Arts and Sciences of Connecticut.

NOTES AND QUERIES.

LEAD-POISONING IN CANNED VEGETABLES.

To the Editor of THE MEDICAL NEWS.

SIR: In the report of one of Dr. Billings's lectures on "Municipal Hygiene," as published in THE MEDICAL NEWS of December 22, 1883, there occurs the following sentence, which requires an explanation from me.

"A few cases of lead-poisoning have been reported (one, by the way, in THE MEDICAL NEWS for September 8, 1883, by a Maryland physician; but since, Dr. Billings has had those cans examined by and analyzed under the supervision of Prof. Remsen, and no trace of lead could be found in the contents)." At the time Dr. Billings asked me for some of the corn for examination I was only able to procure one out of the four dozen cans put up by the family poisoned; the rest having been consumed or thrown away. I am sorry I could not have sent him more than the one, as my own examination showed that lead was not present in the contents of all the cans. I examined three of them. One of these gave only a brownish discoloration with sulphuretted hydrogen, and I did not carry my examination further, as that delicate test did not show the presence of lead.

The contents of the other two gave the characteristic reactions with sulphuretted hydrogen, ammonium sulphide, potassium iodide, and potassium chromate. As I was careful to have pure reagents and to follow carefully the directions for qualitative analysis, given in the standard works on the subject, I am certain lead was present in the contents of two cans.

I also ascertained there were two different lots of cans purchased.

This explanation is sent only in the interest of truth, and to aid in those investigations that are taking place in this country and Europe to detect danger to the public health, if any exists, from the use of canned food.

WM. E. MAGRUDER, M.D.

OLNEY, MD., January 4, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 7 TO JANUARY 14, 1884.

BROWN, P. R., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Huachuca, A. T.—*Par. 9, S. O. 119, Department of Arizona*, December 27, 1883.

EGAN, P. R., *First Lieutenant and Assistant Surgeon.*—Upon reporting of relief to proceed without delay from Fort Huachuca, A. T., to Fort Apache, A. T., and report to the commanding officer for duty at that post.—*S. O. 119, Department of Arizona*, December 27, 1883.

ORIGINAL LECTURES.

THE TREATMENT OF SYPHILIS.[1]

A Clinical Lecture.

BY PROF. DUJARDIN-BEAUMETZ.

GENTLEMEN: In the exposition which I desire to make of the treatment of syphilis, I shall endeavor to be as brief and as practical as possible. I shall, then, put aside the great questions which a consideration of treatment raises, and especially those pertaining to public hygiene and prophylaxis which are so earnestly discussed to-day, and shall concern myself exclusively with the means which will enable you to cure as speedily as possible the various manifestations of venereal disease.

Syphilis is unfortunately a malady whose frequency increases daily, and whose symptoms you will in your practice have to combat a great many times.

I shall not, then, discuss before you the origin of venereal disease. It is probable that, like the greater number of diseases which afflict humanity, syphilis was known in the first periods of the human race, and if we may credit Parrot, the prehistoric man was not exempt from it. Nor shall I discuss the necessity of mercury in the treatment of syphilis; this question seems decided at the present day, and it would be to gainsay the clearest evidence not to admit the efficacy of mercurials in this disease. I am well aware that abuses have been made of this remedy; that not all cases of syphilis are curable by quicksilver; that the treatment is not suitable to all periods of the malady; but what I cannot understand is the obstinacy of a small, though influential, number of physicians, who refuse to acknowledge, as demonstrated, the marvellous action of mercury in a great many cases of syphilis.

It suffices to have been an attentive observer, during one's practice, of a few cases of syphilis with cerebral complications of great gravity, and to have seen them disappear as by enchantment under the influence of an energetic mercurial course, to compel one to admit, without reservation, the therapeutic power of mercury in syphilis. I am going, then, to set forth at some length the fundamental principles of this hydrargyrate medication.

Considered by the writers of antiquity as one of the most energetic poisons, mercury was used externally by the Arabs; Rhazes recommended mercurial applications as part of the treatment of tinea, of scabies, of the mange, and of all wounds of bad nature, and as it is the property of syphilis to produce cutaneous ulcers of foul aspect, it is easy to understand how, from the appearance of the epidemic of syphilis at the end of the fifteenth century, this medicament came to be used in the treatment of these sores. It is then a matter of history that Marcellus Cumanus in 1495, Gasper Torella in 1497, Conrad Gilini still later employed mercurial ointment in the treatment of the grave cutaneous affections which were observed in France and Italy as a sequence of the siege of Naples.

The introduction of mercury into practice as an internal remedy was of later date, and it was not till 1536 that Matthiolus dared prescribe it internally for syphilis, and since this epoch down to the present time, the medical profession has not ceased to administer this medicament, and to note its good effects. Notwithstanding the multiplicity of works on the subject, we are ignorant of the *modus operandi* of this remedy, and while no medicine is in so general use in syphilis, there is none whose physiological action is more obscure. I am nevertheless going to give you some information which we possess relative to the ways of absorption and elimination of mercury, and I will do this, taking as my principal guide the remarkable work which my colleague in this very hospital, Dr. Hallopeau, has devoted to this medicament.[1] Mercury may penetrate the economy, either by the digestive tube, by the respiratory passages, or by the skin, and therapeutics utilizes all of these ways.

There has been much discussion about the penetration of mercury by the skin. It is known, in fact, that quicksilver when finely divided, as it is in mercurial ointment, may enter the economy through the skin, when not devoid of its epithelium, and this is one of the methods by which salivation may be most rapidly produced. How does this penetration take place? Some, as Overbeck, Eberhards, Oesterlen, have pretended that mercury in the metallic state penetrates the subcuticular vascular network. Others, as Rindfleisch, have maintained that this penetration of mercury in the metallic state is impossible, and that it is only after having been transformed into a soluble chloride by the sudoral secretion, that quicksilver enters the economy. The recent experiments of Fleischer give much support to these last views.

It is then in the state of chloride, and especially of bichloride, as Mialhe[2] affirms, that all mercurial prepa-

[1] Translated from advance sheets by E. P. Hurd, M.D., of Newburyport, Massachusetts.

[1] Hallopeau. De Mercure: Thesè d'agregation. Paris, 1880.

[2] Mialhe has pretended that mercury does not penetrate the system except in the state of bichloride, or in the form of an alkaline hydrargyrate-chloride. The protoxides undergo transformation, he thinks, into protochlorides, and then into bichlorides.

Voit admits the same thing—to wit, that the suboxides undergo transformation into calomel, and the oxides into bichloride; these last unite with the chloride of sodium and albumen of the blood.

The recent investigations of Bucheim and of Ottingen and those of Otto Graham make it appear probable (contrary to the views of Mialhe) that the protochloride combines with albumen to form an assimilable albuminate of protoxide of mercury.

Bellini has studied the modifications which the chlorides, the bromides, and the iodides undergo. Calomel, according to him, dissolves in the stomach and in the intestines under the influence of chlorides and lactic acid, being transformed into a double chloride of mercury and sodium and into lactate of mercury. The iodides and the bromides undergo a similar change, being transformed into double salts under the influence of the alkaline chlo-

rations enter the blood, combined, be it understood, with the albumen of the blood, thus constituting a double albuminate or peptonate of hydrargyrum and of sodium.

When once it has penetrated the blood, mercury, after having sojourned a variable time in the economy, is eliminated by divers emunctories, in particular by the kidneys, by the feces, by the milk, by the sweat, and by the saliva. The duration of this elimination depends on the duration of the mercurial treatment, and when this has been very prolonged, one may find mercury in the urine for several weeks after the treatment has been discontinued. Mercury seems, in fact, to fix itself in different viscera, and in particular in the liver.[1] It has even been maintained that it is this fixation of mercury in the bowels which provokes those osteocopic pains so frequent in the advanced periods of syphilis. This interpretation is absolutely erroneous, for there are syphilitic patients who, never having followed any mercurial treatment, have osteocopic pains of the most violent kind, and these pains seem to be mitigated under the influence of mercurial preparations.

Among the channels for elimination of mercury, there are two which interest the therapeutist—the mammary and the salivary glands. The fact of elimination by the milk, enables us to apply to the treatment of syphilis in the new-born child, the administration of mercury to the nurse. The fact of elimination by the saliva explains the cause of the salivation which so frequently attends the mercurial treatment. It is, in fact, maintained that it is the presence of chlorides of mercury in the saliva which is the point of departure of the irritation of the mucous membrane of the gums. At the same time this point of pharmaco-dynamic action demands to be studied anew, for the salivation seems to depend especially on the mode of administration of the mercury. Very easily provoked by cutaneous inunctions, it is exceptionally produced by hypodermic injections.

Can we find in the physiological and toxicological action of mercury the explanation of its anti-syphilitic action? Unhappily, no; and the study of mercurialization, whether slow and chronic or sudden and acute, observed so often in men who work in industries where mercury is in use, does not furnish us any data for the solution of this important therapeutic question.

It has been said that mercury acts on the blood-globules and the plasma; this may be true in the normal state, and when it acts as a poison. But this is the very opposite of what takes place in syphilitic patients, where one constantly sees under the influence of a well-regulated treatment, the number of red globules augment, as well as their richness in hæmoglobin. The experiments of Wilbouchewitz, of Moscow, of Keyes, of Robin, of Schlesinger, are absolutely confirmative in this respect. Mercury cures syphilitic anæmia, but it is powerless to benefit other anæmias. It is necessary then to admit that mercury possesses a specific property in the treatment of syphilis, and we are obliged to content ourselves with the data which are furnished us by empiricism and tradition concerning the antisyphilitic action of mercury.

The absorption of mercury may take place, as I have told you, by three ways: by the skin, by the lungs, by the stomach. Therapeutics utilizes these three modes of introduction, and thence result three different modes of treatment of syphilis: the dermic and the hypodermic method, the respiratory method, and finally administration by the alimentary canal.

Let us examine the advantages and disadvantages of each of these methods:

The dermic method is the most ancient. We have seen that it was by applications of mercurial ointment that attempts were first made to cure syphilitic sores. This method is still employed at the present day; nevertheless, since the improvements in hypodermic injections of our time, the dermic method is much less used than formerly. Frictions with mercurial ointment, if they cause mercury rapidly to enter the economy, have the very serious objection of speedily determining salivation. For these inunctions mercurial ointment is used; the "fortior" and the "mitior." The stronger ointment is called the Neapolitan cerate. As it is generally admitted that mercury does not penetrate the system till it has been subjected to the action of the sudoral secretion, the rule has been to practise these inunctions on parts of the skin where the sweat glands are the most numerous, as in the arm-pit, the groin, the soles of the feet. Denis Dumont has even proposed, under the name of *Neapolitan hose*, a very convenient method for making these applications, especially when the patient wishes to conceal the treatment which he is pursuing. This method consists in making the patient put on, at bedtime, a pair of *hose* or *long stockings*, the interior of which has been medicated with Neapolitan ointment. As for the frictions, they are repeated once or twice a day, according as one wishes to obtain a more or less rapid action. The rubbing lasts from five to ten minutes, and when once finished, it is the custom to wash the parts where the inunction has been made, to avoid the local irritant action determined by prolonged application of the mercurial pomade.

---

rides and lactic acid. A part of these salts enters the circulation, another part is transformed into sulphide of mercury in the large intestines, and eliminated in the feces. (Rindfleisch, Arch. de Dermatol., t. ii. p. 309. Overbeck, Mercure und Syphilis, Berlin, 1861. Hallopeau, Th. d'agregation, 1878. Voit, Physiologie, Chemische Untersuchungen, 1 Heft, Augsbourg, 1858. Blomberg, Nagra ord om quicksellfvrets absorpcion, af organismen, 1867.)

[1] The elimination of mercury is effected by the kidneys, intestines, mammary glands, perspiratory and salivary glands. The utility of this last kind of elimination has been much disputed of late years, yet Bernaski has determined the presence of mercury in the saliva taken directly from Steno's duct.

Personne, Binz, Lewald, and Klink have found mercury in the milk of nurses submitted to mercurial treatment.

Riedérer has examined experimentally the quantity of mercury eliminated by the different emunctories. In an animal which had taken, in twenty-nine days, nearly two grammes of mercury, during this time four per cent. was found in the feces, nine per cent. in the urine, and during the succeeding eighty-one days there was still found in grammes and fractions of a gramme, .0568 in the feces, .0040 in the urine, and .0026 in the liver.

Mayencon and Bergeret have studied the rapidity of elimination of the mercurial preparations. Experiments show that the greater part of the medicament is immediately eliminated in the urine, and that another part, after having become fixed in the tissues, is eliminated very slowly and insensibly, insomuch that several days after the cessation of the mercurial treatment the presence of mercury is detected in the urine. (Bergeret and Mayencon, "Clinical Means for Recognizing Mercury in the Excretions, and principally in the Urine;" Lyon Medical, t. iv., 1873, p. 179.)

Mercurial baths form a part of the dermic method of treatment. Here the penetration of the mercury into the system is much less active, and if baths of corrosive sublimate render some service in therapeutics, it is simply by their local action. These baths, the only mercurial baths employed, contain ʒv of corrosive sublimate for a full bath.[1] You can add to these baths common salt or sal ammoniac. It is also the local effect that is sought for when the various mercurial plasters are prescribed, the most known of which is that of Vigo.

The hypodermic method of the treatment of syphilis is of quite recent date, and thanks to the improvements which have been made in the liquids used in these injections by Martineau and Delpech, this method, which has all the advantage of the dermic mode without the disadvantages, namely, a very prompt and energetic action, without salivation, tends to take the place of the dermic method. It was Hebra and Charles Hunter who, in 1863, first practised sublimate injections in the treatment of syphilis, and in 1868 Liegeois popularized this method in France, but these first trials were unsatisfactory, and the method was abandoned. Corrosive sublimate is in fact very irritating, and it is easy to see that these subcutaneous injections, very painful as they are, might cause grave local lesions. For the solutions of corrosive sublimate and of chloride of sodium, which were employed by Hebra, Charles Hunter, Lewing, Liegeois, and Tachard, it was proposed to substitute the cyanide or the bicyanide of mercury as Mandelbaum and Guntz proposed. Others, as Luton and Fürbringer, advised injections of metallic mercury, rubbed up with glycerine and gum arabic. But all these solutions were always painful, and it was only by combining albumen and peptones with corrosive sublimate that solutions were obtained having a very feeble irritant action. This is what has been accomplished by Neumann, Bamberger, Terrillon, and especially Martineau and Delpech, who, in uniting chloride of ammonium with peptones and with corrosive sublimate, have made a solution of mercuric ammoniacal peptone which is absolutely neutral, keeps perfectly, and rarely determines local lesions when properly injected.[2]

[1] The formula of corrosive sublimate baths is as follows:

1.

℞.—Bichloride of mercury, ... 2 parts.
Alcohol, ... 5 "
Distilled water, ... 200 " —M.

2.

℞.—Bichloride of mercury, ... 3 parts.
Chloride of ammonium, ... 3 "
Water, ... 1000 " —M.

3.

℞.—Bichloride of mercury, ... 1 part.
Chloride of sodium, ... 1 "
Warm water, ... 100 " —M.

[2] Neumann maintains the advantage of subcutaneous mercurial injections; he lauds especially solutions of corrosive sublimate with albumen and peptones as being but slightly, if at all, irritating. Bamberger uses the following solution: To 20 parts by weight of albumen, as pure as possible, add 30 parts by weight of distilled water, and filter. Mix 10 parts by weight of this albuminous solution with 6 parts by weight of a 5 per cent. solution of corrosive sublimate, and 6 parts by weight of a 20 per cent. solution of common salt, and 8 parts by weight of distilled water. Let it stand two days, and filter with care. 320 grains parts by weight of this solution contain gr. ij$\frac{3}{10}$ of metallic mercury.

It is necessary, in order to avoid accidents, to make these injections as deeply as possible. And here, as in the case of subcutaneous injections of chloroform, you ought to thrust your needle perpendicularly into the tissues; therefore, it is almost always in the hips that we make these injections. In the thousands of subcutaneous injections which Martineau has performed in the Hospital of Lourcine, he has never observed any grave accidents. At the same time, it is well to remember that in the majority of cases these injections are painful, and that they leave behind them an induration of tissue which lasts for some time. There are even patients, females especially, so hyperæsthetic that they cannot bear these injections. Despite these cases, which are exceptional, the hypodermic method is excellent, especially in hospital practice, being sure and speedy. In private practice this mode of treatment is more difficult to carry out; you ought then to reserve it exclusively for grave cases, where you want a prompt and energetic action, as in syphilis of the brain and spinal cord. These injections contain in each syringeful, as you well know, gr. ⅛ of corrosive sublimate. When you do not wish to go to the trouble of preparing the rather complex solution of Delpech, you can prescribe subcutaneous injections made as follows:

℞.—Powdered peptone (Catillon), . 3 parts.
Chloride of ammonium, pure, . 3 "
Corrosive sublimate, . . . 2 "
Glycerine, ... 50 "
Water, ... 150 " —M.

Terrillon has made trials of hypodermic injections of the peptonates of mercury. He made use of Bamberger's solution, which is as follows: Take of meat peptones, gr. xv; water, f ʒj$\frac{6.9}{100}$. Filter; and add: Solution of corrosive sublimate (1:500), f ʒv$\frac{4.4}{100}$; solution of chloride of sodium (20 per cent.), f ʒiv$\frac{3.3}{100}$. Distilled water sufficient to make f ʒiij$\frac{3.5}{100}$.

Each f ʒvss of this solution contains gr. ⅛ of mercury. In combination with peptones, these injections cause no pain, if made deeply in the subcutaneous tissue. Delpech has advised the following formula for the preparation of mercuric ammoniacal peptones. Take of

Dried peptone (Catillon), ... 3 parts.
Chloride of ammonium, ... 3 "
Mercuric chloride, ... 2 " —M.

This powder is one-fourth part corrosive sublimate; hence one gramme contains gr. iij¼ of corrosive sublimate. From this formula divers preparations are made:

1. Hypodermic injections—

℞.—Powder of peptonate of mercury, . . 1 part.
Distilled water, ... 50 "
Glycerine, ... 10 " —M.

Each syringeful of this solution corresponds to gr. ⅛ of corrosive sublimate.

2. A solution which is taken internally—

℞.—Powder of peptonate of mercury, . . 1 part.
Distilled water, ... 200 "
Glycerine, ... 50 " —M.

Every gramme of this solution contains 1:1000 of corrosive sublimate.

3. Pills—

℞.—Powder of peptonate of mercury, . . ʒss
Opium, ... grs. viij
Powder of guaiac, ... ʒss
Powder of ext. licorice, sufficient to make 100 pills.

Each pill contains gr. $\frac{1}{15}$ of corrosive sublimate.

Each syringeful of this solution contains gr. ⅙ of corrosive sublimate. These injections are practised every day or every second or third day, according to the urgency of the case, and I shall return presently to the doses, when I come to the syphilitic complications.

The respiratory method, which has for its basis mercurial inhalations, is of very ancient origin. It has been restored to practice the past few years by Langston Parker, of England, by Bumstead, of New York, and by Horteloup, in France. This method, which may be called *dermo-pulmonary*, consists in placing the patient in a box in which are burned troches containing cinnabar or corrosive sublimate. The penetration of vapor is effected chiefly by the lungs. The box, being of loose construction, allows the fumes to escape into the outside air. I have never employed this *dermo*-pulmonary method, but it seems to me every way inferior to the hypodermic mode, and is certainly less precise and sure. In fact, this kind of treatment is not likely ever to be popular.

I come now to the last method of administration, namely, that by the alimentary canal, which is by far the most available and practical. Mercury is employed under all its forms;[1] metallic mercury, the most common preparation of which is the blue pill; bichloride of mercury, which is the active ingredient of the liquor of Van Swieten; the pills of Dupuytren; and the ordinary solution of the British Pharmacopœia; the protiodide (Ricord's pills); and the biniodide, which is contained in the syrup of Gibert. These are the forms most in use in our country. There are, however, a prodigious number of hydrargyrate preparations in the shops of pharmacists—pills, solutions, potions, pastilles—whose formulæ you will find in most of your treatises on syphilis. What salt of mercury ought you to choose? It may be replied that all the preparations I have just enumerated are suitable. At the same time, for my part, I prefer the bichloride and biniodide, to all the others, and I consider the bichloride, and especially the solution of Van Swieten which contains it, as the most active in the first periods of syphilis, of all preparations given by the mouth. This preference is not only based on the results of my practice, but it is also in conformity with what we know of the introduction into the economy of mercury, which always enters the circulation in the state of bichloride. If you employ the bichloride, whether in the form of Dupuytren's pills or Van Swieten's liquor, I advise you always to administer these preparations with food or with milk; you will thus avoid, as far as possible, the irritant local action of corrosive sublimate on the alimentary mucous membrane. Such are the principles of the mercurial treatment of syphilis. I must now point out certain rules which should guide you in this treatment—when you ought to commence it, and when you ought to leave it off. But before proceeding to this part of my task, I must say a few words about the accessory modes of treatment.

(To be concluded.)

[1] Following are some of the forms of administration of mercury by mouth:

1. *Blue pills.* The formula is too well known to need repetition here.

2. *Sedillot's pills.* Each pill contains gr. iss of mercurial ointment, with gr. $\frac{9}{10}$ of castile soap, and gr. $\frac{6}{13}$ of licorice powder.

3. *Bichloride of mercury.* Van Swieten's formula is as follows:

℞.—Bichloride of mercury, ... 1 part.
Rectified spirits, ... 100 "
Pure water, ... 900 " —M.

One teaspoonful contains gr. $\frac{1}{13}$ of corrosive sublimate.

4. *Mauriac's modification of Van Swieten's liquor—*

℞.—Spirits of peppermint, ... 4 parts.
Hydrarg. bichlorid. . . . . 1 "
Alcohol, ... 95 "
Syrup of morphia, ... 250 "
Orange-flower water, ... 100 "
Distilled water, ... 50 " —M.

This preparation is twice the strength of Van Swieten's.

5. *Dupuytren's pills—*

℞.—Hydrarg. bichlorid., ... gr. ⅙
Ext. opii, ... gr. ⅓
Ext. guaiac, ... gr. ⅔ —M.
For one pill.

6. *English anti-venereal drops—*

℞.—Crystallized perchloride of iron, . . 1 part.
Corrosive sublimate, ... 1 "
Distilled water, ... 1000 " —M.

Every f℥ij contains gr. ⅙ of corrosive sublimate. A medium dose, one teaspoonful.

7. *Brazilian electuary of Carneiro, containing calomel—*

℞.—Calomel, ... gr. xv
Powdered sarsaparilla root, . . . ℥vij
Powdered senna, ... ℥iijss
Simple syrup, sufficient to make an electuary.—M.

Every f℥ijss contains gr. $\frac{1}{15}$ of calomel. Full dose, ℥ijss.

8. *Ricord's pills—*

℞.—Hyrarg. protiodid. . . . . gr. xlv
Ext. lettuce, ... gr. xlv
Ext. opii, ... gr. xv
Ext. hemlock, ... ℥iss —M.
F. S. A. 60 pills.

9. *Formula of French Codex—*

℞.—Hydrarg. protiodid. . . . . gr. ¼
Ext. opii, ... gr. ½
Conserve of roses, ... gr. ½
Licorice root, sufficient for one pill.—M.

10. *Gibert's pills of biniodide—*

℞.—Biniodide of mercury, ... gr. i½
Iodide of potassium, ... gr. lxxv
Pulv. acacia, ... gr.vijss—M.

F. S. A. 20 pills. Two of these pills contain gr. ⅙ of biniodide of mercury.

11. *Syrup of Gibert—*

℞.—Biniodide of mercury, ... 1 part.
Iodide of potassium, ... 50 "
Water, ... 50 "
Simple syrup, ... 2400 " —M.

Every tablespoonful contains gr. iij¾ of biniodide.

ORIGINAL ARTICLES.

A CASE OF WORD-BLINDNESS, WITH IMPAIRMENT OF THE FACULTY OF SPACE ASSOCIATION.

BY ALLAN McLANE HAMILTON, M.D.,
PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POLYCLINIC, ETC.

IT is rare indeed to find the sudden development of an aphasia the immediate expressions of which are recorded by the patient himself, and we are usually obliged to depend upon the statements of

the patient after his recovery, or those of persons with whom he may have been at the time of the cerebral accident. It is true that evidences of agraphia are sometimes disclosed by the letters of the patient, but I have never met with an instance which so beautifully shows the embarrassment as that I now present, the patient being a printer, who was engaged in setting up a legal brief when he was attacked. Very fortunately the copy was preserved, and I am enabled to reproduce the printed column, with all its original errors, with corrections made by the patient during his convalescence. It will be seen that the patient's difficulty began rather suddenly, and it was not until the seventieth answer was reached that he began to make mistakes, and as he advanced his confusion increased.

The case also presented various curious symptoms which I am convinced are of the utmost importance, as they show an impairment of what may be denominated the sense of fitness, or direction, and an inability to properly appreciate the relations of space.

William H. M., is 33 years old, a printer, and a man of excellent habits. He has not had syphilis and there are no evidences of cardiac or lead disease; his family history is good, his mother and father being alive and well. He is a bright, skilful workman, and has been engaged at "book-work." He made few mistakes in composition, and was looked upon as an industrious, intelligent man. According to his own story he had had domestic trouble for a short time previous to October, 1881, was worried, and lost flesh and strength. He, for several of the early days of October of that year, felt distressed about the head, and had slight vertical pain, but no vertigo. Upon the afternoon of the 10th he had a sense of impending trouble, but no idea of his real condition until the foreman of the shop called his attention to the remarkable character of his work. His "stick" contained matter that was full of mistakes known to the craft as "doublets." In almost every line he had repeated one word several times, and many others were transposed. In other places the types were upside down. He could not correct his mistakes, but made fresh blunders. At half-past five he still felt badly, and was obliged to stop work. He went to a neighboring eating-house, where he had frequently dined, and though the door-knob was large and easily reached, he had considerable difficulty in finding it. After entering the place he staggered and could walk only with difficulty, and dragged his right foot. He could not ask for what he wanted, although the bill of fare was before him, and he was considered drunk. He managed to leave the place, and went home; his right leg remained numb and weak, and he fell frequently. He remembered that while walking he was inclined to proceed in a semicircular direction, mainly toward the right, and his face was turned to that side. He next became unconscious and remembered nothing until next morning, when he was found by persons who had broken into his room. He heard all questions, but could not reply. He could move his right leg feebly, as well as his arm. He was next taken to the Chamber Street Hospital, where he remained for two days. So far he could not speak, but within a month began to talk, but could not read. He could repeat words, however, after another person.

I first saw the patient about the end of February, 1882. He was a man of spare build, rather poorly nourished, and had an annoying cough. He presented a poorly marked paresis of the entire right side, but there was very slight clumsiness in his gait. The dynamometer showed that he could force the index about twenty degrees further around on the left side, and his hand-grasp was stronger on this side. The right angle of the mouth was lower than the left, and there were transitory fibrillary tremors of the facial muscles. No lead-line was to be found, and there was no marked extensor paralysis—he being able with his hands upon the table to lift a considerable weight (a pound and a half) placed upon the dorsal surface of the fingers. Tactile sensibility and temperature were diminished on the right side. He had occasional frontal headaches. The left pupil was very slightly dilated; there was no diplopia. He had control over his tongue, and there was no deviation of the uvula, or irregularity of fauces. The reflexes were all diminished on both sides. There were no darting or stabbing pains. There was no cumulative tremor when a cup or glass was carried to his mouth. The functions of the pelvic organs were unaffected. Specific gravity of urine 1020; normal. Heart and lungs healthy, with exception of slight bronchitis. Shortly after his seizure his right arm would often be spasmodically drawn across the chest, and at the same time there would be slow spastic flexion of the leg. These seizures were often repeated and of short duration. An ophthalmoscopic examination was made which revealed inflammatory changes in the vicinity of the macula of right eye. In the left large patches of retino-choroidal atrophy were found. Both optic disks were atrophic.

The patient was emotional, and sometimes cried quite easily. He was able to converse intelligently, and memory was apparently unimpaired, and he had had no hallucinations or delusions. The interesting feature of his disease was shown when he attempted to read. He did so with great difficulty, going over the ground slowly and referring to previous words whose images he seemed to have retained. He read substituted words which in length and form resembled in some degree those of the printed matter; for instance, *New Haven* for *New Hampshire; situate* for *stated; continue* for *countersign; desirious* for *declares; Alderman* for *Anderson*, etc.; but with proper names he had the greatest difficulty: *George W. Hunt*, a name printed in the paper I asked him to read, was rendered *John H. Hunt*, and he made several attempts and finally gave up in disgust. He prefixed unnecessary articles to whatever words he was asked to read. He knew the denomination of coins from their size and color, but could not add them. Though his trade is one that should make him expert in estimating distances, he could not when asked to make a line of certain length approximate the true space. He always fell short of the required distance. A line three-eighths of an inch in length was said to

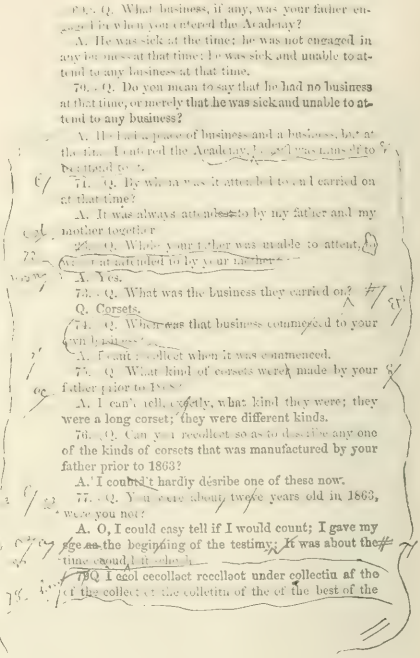
represent half an inch, and three-fourths of an inch, one inch. He had no idea of adjustment. When told to place his index-finger on the figure twelve on the dial of my watch he could not do so readily; and when told to find a point midway between twelve and six, he selected four. It must be remembered that in this case there were no changes in the muscles of the eyeballs, no diplopia or hemiopia; and I looked for these symptoms carefully. He repeated his mistake over and over when repeated tests were tried. Upon more than one occasion he made singular blunders in the location of objects. One of his duties was to place the knives and forks at the patients' plates. He once or twice placed two forks or two knives at the same plate. At other times he placed the knife and fork at one plate with the points reversed, while at other plates they were properly arranged. When his attention was called to these things he always expressed great surprise or annoyance, but invariably repeated the mistakes when he next attempted the act.

By accident a very curious mental condition was discovered—a loss of appreciation of direction or space by association. As a rule, the normal individual, when aware of the direction of one point of the compass, is able to designate the others. If he is placed with his face to the North, he knows that the East is on his right hand, and the West on the left, and the South behind him. In this patient the case was different, and both Dr. O'Brien and myself repeatedly tested this lost faculty. It made no difference how he was placed, for even with the knowledge of one point, he was apt to transpose all the others. He knew which was his right hand, and which was his left, but could not associate them with the direction. Even when three of them were properly designated after prompting, he would be apt to reapply a term already used to the fourth. This blunder was not the result of ignorance; he had a fair knowledge of geography, he was not insane, and his memory of recent affairs was unusually good. There was some loss of taste and smell.

This man slowly improved, and was discharged with no trace of asemasia, but with slight weakness of the right side. Before he left the hospital he presented us with the appended slip which he had a few days before corrected.

I related this case to the members of the Section in Practice of Medicine of the New York Academy of Medicine, and my apology for referring to it again is the production of the proof-sheet, which gives the case greater interest than its bare recital. Dr. Seguin at that time said that he had himself seen several cases in which the peculiar loss of the faculty of location had been a feature, and in one case the patient, who, by the way, had no agraphia, was very apt to turn things the wrong way or upside down. The patient, when he attempted writing, would turn the pencil around two or three times, and would invariably stop with the pointed end up.

I have noticed this peculiar symptom in other cases. In one—that of Dr. Allin—where there was word-deafness, and a lesion of the occipital convolution on the left side, the patient was very liable to reverse things. Dr. Ball, who described the case, says: "The only exception to this fact (the spacial relation of objects,) was a singular symptom which annoyed him for several months, viz., a



tendency to reverse the natural position of objects which he handled, such as table-knives, spoons, pencils, canes, etc. He immediately recognized his mistake, however, and corrected it, but always spoke of the inclination as irresistible." Dr. Seguin, in commenting upon this case, was disposed to account for the patient's trouble as an impairment of muscular sense, and he admits that he has never met with such a condition before. "If he did not use his eyes in prehending objects with his right hand, he would find that he had seized them by the wrong end. He sometimes found himself standing with the head of his cane on the ground and its point in his hand. Frequently, in my presence, he essayed to grasp a pen or pencil with his head turned away, and repeatedly he found himself holding the object by the wrong end, and after this turning it over three or four times to get its outlines." I have seen another case in which the same difficulty existed, the patient taking his cane by the wrong end, and he often turned his latch-key, endeavoring to insert the wrong end in the keyhole. He *always* buttoned his clothing improperly

—getting the buttons in the wrong holes. In this case there was no apparent word-blindness or deafness. The patient was slightly paretic on the right side, there was an exaggerated knee-jerk upon that side, and other indications of a slow arterial degeneration, and a lesion probably in the cortex.

The lost sense of direction and localization could hardly be described under the head of *apraxia*—a term which Kussmaul applied to a state in which "the memory for the uses of things is lost as well as the understanding for the signs by which the things are expressed."

PROF. CARL BRAUN'S ANTISEPTIC OBSTETRICAL METHODS.

BY W. W. JAGGARD, M.D.,
OF CHICAGO, ILL.

PROF. CARL BRAUN deserves a prominent place among the great men who have aided the development of antiseptic methods in obstetrics. Although no micrococcus, bacillus, or spirillum owes its name to his researches, antiseptic methods were practised with critical exactness in the Vienna Lying-in Hospital before the discoveries of Weber, Billroth, Pasteur, Schwann, Koch, and Lister were made known.

Boër, Braun's immediate predecessor, Smellie's pupil, imbued with English obstetrical ideas—at marked variance with Continental doctrines—effected a partial substitution of German by English methods in the Vienna Lying-in Hospital, which resulted in the rejection of obsolete instruments, cumbersome obstetrical beds, chairs, tables, and pillows, the heritage of previous centuries.

From March, 1849, to September, 1853, Braun acted as sole assistant in the clinic, assuming his present position in 1856. Owing to the precedent established by Boër, and to Braun's individual convictions, English notions in obstetrics have flourished in Austrian soil, and to-day there exists a remarkable identity of obstetrical doctrines in Vienna and the United Kingdom, presenting a striking contrast to the teachings of Germany, France, and America.

Endowed with a philosophical intellect, developed by broad, profound, critical study and a fabulous experience of thirty-four years of uninterrupted labor in the largest existing obstetrical hospital, Braun has made invaluable contributions to every department of obstetrical science.

It is the object of this paper to sketch briefly one of these contributions: Vienna Antiseptic Obstetrical Methods.

I. *Hospital Ventilation.* Ten wards of the so-called new wing of the Vienna General Hospital have been used, *without interruption*, from 1834 to the present time, for the practical instruction of physicians in obstetrics. In 1873 the obstetrical wards were divided into three departments. The first and second clinics, under the control of Profs. Carl Braun and Josef Späth, respectively, were devoted to the practical instruction of physicians, while the third clinic was assigned to Prof. Gustav Braun for the education of midwives. In each clinic one ward, termed the lying-in chamber, containing eighteen or twenty beds, is set apart for parturient women, while pregnant and puerperal patients occupy the remaining rooms. The reception of women in labor alternates, every twelve hours, between the three clinics, so that once in three days there is an interval, when the beds of each lying-in chamber have either no occupants at all or a few accidental cases coming from the "pregnant" wards. This period of time is technically termed "empty day," and exercises an important function.

The paramount importance of perfect ventilation received immediate recognition upon Braun's accession to the control of the hospital.

Profs. Braun,[1] Späth, and Böhm devised, in 1860, and carried into execution in 1863, a system of hospital ventilation and heating, which has continued, with few modifications, in effective operation for twenty years. This system consists essentially of a large furnace, constructed in each ward, and a system of air-conduits, which can be used for change of air, with or without heat. The furnaces draw well, heat the air streaming into them to 40–80° C., and spread through all the wards a very agreeable, lasting, refreshing, *odorless* warmth; they heat great quantities of air, 80–200 cubic metres per hour and individual, of cold, fresh air in severest weather of −20° C.; preserve a constant temperature of +16–20° C.; give eight times the change of air obtained by earlier methods; save twenty-five per cent. in money in comparison with former modes, and approximate the results of the best modern centralization methods by steam or hot water.

Simple anemometrical indicators are placed in the vertical air-tubes to determine the direction and velocity of air-currents, and to regulate the register of the valves in the conduits of the entering and departing air.

Drying and warming chambers for heating linen to 100° C., are connected with small furnaces in each ante-room. Each ward is thus heated and ventilated separately, while the excess of caloric is utilized in drying and heating linen. Water-closets of an approved English model are connected with every ward.

Owing to the order of receiving women in labor, the lying-in chamber is vacated every third day, the large windows upon both sides of the room are thrown open, and every article of furniture or apparel is abundantly aired.

Pettenkofer's precept, that each individual requires, hourly, a minimal allowance of sixty cubic metres of fresh air, meets with practical recognition in this method of ventilation. Braun says upon the subject of hospital ventilation (*Gynäkologie*, p. 884):

"I have arrived through practical observation at the recognition of the fact, that the rapid and effective prevention of putrefaction by means of generous and

[1] Braun's communication, Medizin. Jahrbüch. der Gesellschaft der Aertze in Wien, 1874.

adequate ventilation, is to be regarded as a good prophylactic rule against puerperal fever; that not the greater number of puerperal women who are annually cared for in a hospital, and not the greater number of puerperal women in one room, but the insufficient change of air in a cell for one individual in the smallest hospital, is to be regarded as the important factor in the spread of puerperal fever; that puerperal women, therefore, in order to be effectually guarded against puerperal fever, must be isolated, not by insulated houses and gardens, not by stone walls, but by the continuous conveyance of large quantities of fresh, pure, warm air by means of a cheap, practicable, easily executed method."

The Braun-Späth-Böhm system of ventilation, in comparison with other modes, has the advantage of cheapness of construction and operation; it is peculiarly adapted to old buildings, and in respects of simplicity, adequacy, durability, ease of operation, answers to the highest demands of hygiology. This system of ventilation is now in active operation in the General and Rudolph's Hospitals in Vienna, in the Prague Lying-in Hospital, and in many foreign institutions of similar character.

Recently the administration of the obstetrical department has been separated from that of the General Hospital, and special laundries have been established. The wooden bedsteads have been replaced by iron frames, and the straw ticks have been substituted by iron wire mattresses. Each pregnant, parturient, or puerperal woman receives, as her bed furniture, woollen blankets, clean linen sheets, a rubber blanket, and a pillow filled with horse-hair. Separate bath-tubs and water-closets are assigned to the patients according as they are pregnant, parturient, or puerperal. Pure mountain water is supplied in abundance to every ward. Blankets, and woollen articles of clothing are disinfected in a large, walled-in chamber, by means of superheated air. Finally, there is an annual house-cleaning and white-washing, of more than New England thoroughness.

II. *Treatment during last weeks of Pregnancy.* Upon admission into the hospital, healthy pregnant women are separated from those who have an abnormal temperature, or present other pathological appearances. During the period prior to confinement—a space of four or six weeks—the pregnant woman is compelled to take baths at regular intervals, and her axillary temperature is carefully noted. Her last act before entering the lying-in chamber, is to take a warm bath, in which soap is vigorously applied.

III. *Treatment during Parturition.* Upon entering into the lying-in chamber in the first stage of labor, the woman is put to bed, and her axillary temperature noted in the protocol. If her temperature is pathological, she is transferred at once to another ward. If her temperature is normal, that is, at or below 38° C., she is examined by the attending physician or midwife. Vaginal examination is permitted an individual upon the conditions: (1) that for the space of twenty-four hours preceding, he has not been within the sphere of contagion of any zymotic disease, and that his hands have not come in contact with any wound or cadaver; (2) that his hands are absolutely clean. The importance of the second condition is difficult of exaggeration in a land like Austria, where the minimal consumption of soap and water is attained.

After a vigorous application of soap and nail-brush in a two and a half per cent. solution of carbolic acid, the hands are dipped into a solution of potassium permanganate (twelve grammes to one kilogramme of distilled water), until they are colored a deep brown; they are then transferred to a solution of concentrated commercial hydrochloric acid in water (sixty-five grammes to four hundred grammes of distilled water), which removes the stain of the chameleon mineral and all organic matter still adherent. They are wiped dry upon large linen sheets, which are constantly renewed.

Before making the examination it is customary to dip the exploring finger into a solution of hydrochloric acid in glycerine (two grammes of concentrated, commercial hydrochloric acid in four hundred grammes of glycerine).

During parturition it is usual to douche from time to time the external genitals with some antiseptic fluid, such as a one-fifth per cent. solution of salicylic acid, a one-tenth per cent. solution of thymol, or a two per cent. solution of carbolic acid. In every case of protracted labor, after rupture of the bag of membranes, sitz baths at regular intervals are enjoined.

When operative procedure is indicated, the vulva and vagina are thoroughly irrigated with a two per cent. solution of carbolic acid before the introduction of any instrument. All instruments, including uterine tubes and catheters, are kept submerged in a two and a half per cent. solution of carbolic acid before use. When the use of instruments has necessitated the invasion of the uterine cavity, it is thoroughly irrigated with a thymol solution after separation of the placenta. Apart from the invasion of the uterine cavity by instruments, there are other indications for its irrigation, which will be discussed later.

The hard rubber tube introduced into the cavity of the uterus is about twenty-five centimetres in length, three centimetres in circumference, and terminates in an olive. The irrigator is the one designed by Leiter, and is simply a large, conical glass flask.

Extreme attention is paid to the exclusion of air from the uterine cavity during the process of irrigation. The disinfectant solution is allowed to displace all air within the pipe of the irrigator and the uterine tube before the latter is introduced within the cavity of the uterus. During the irrigation one hand performs gentle friction upon the fundus, through the abdominal parietes. After the completion of the irrigation, a *bacillus*, containing five grammes of iodoform, is introduced within the uterine cavity; an equal quantity is usually placed within the vagina.

Perineal ruptures and episiotomy wounds are carefully cleansed and immediately united by *serres-fines* or sutures. Contused and lacerated wounds of the vagina are painted over with neutralized tincture of sesquichloride of iron, acetic clay, tincture of iodine, Goulard's extract, thymol, or carbolic oil.

All wound surfaces are finally dusted over with iodoform powder. Incidental allusion to the subject of axillary temperature has already been made, but it demands, at this stage, especial notice. The axillary temperature of each patient is taken and recorded at intervals of three hours, during the entire period of parturition. If the temperature becomes abnormally high, the patient is at once isolated. This rule is enforced with rigorous exactness in each department of pregnant, parturient, and puerperal women.

Winckel, of Dresden, first directed attention to the importance of tokothermometry, and proved that skin-temperature was of more constant diagnostic and prognostic moment than pulse or respiration. Braun has abundantly corroborated Winckel's researches, and the clinical thermometer plays a very active part in the first obstetrical department.

In a recent lecture upon this subject Braun said:

"I am perfectly convinced that every parturient woman in a febrile condition on account of endometritis, with or without *tympanites uteri*, possesses the capability of infecting, during her stay in the room, as the result of which she can become the source of extreme danger to her neighbors; whether the transport of the pernicious influence is effected by the examining finger or by the polluted air penetrating the vagina, I should like to leave undecided. I, myself, hold that the one as well as the other mode of transport is possible, and after exploration or operation in a case of septic endometritis, even after the most careful purification and disinfection of the hands, would not venture to examine, upon the same day, a healthy, pregnant, or parturient woman."

III. *Treatment during the Puerperium.* Immediately after labor the soiled linen is removed, and the patient enveloped in linen sheets heated to 100° C. After the patient has recovered from the fatigue of labor, by a brief period of sleep, the midwife cleanses, with a bit of absorbent cotton, the skin of thighs, abdomen, and vulva, and wipes the surfaces dry with a clean, warm towel. Sponges have been for years banished from the clinic. The rules for the further treatment of the puerperal condition are:

1. A rapid healing of the uterine wound is best effected by quiet, restricted diet, and absolute cleanliness. To maintain cleanliness, it is seldom necessary to inject lukewarm water into the vagina, and still more rarely are we compelled to irrigate the uterine cavity.

2. To prevent the resorption of the pus secreted by the uterine surface, it is necessary (*a*) to fill all the bloodvessels to their maximum capacity, by the exhibition of generous quantities of lukewarm, sweetened drinks, (*b*) to avoid depletion by diuretics, diaphoretics, or purgatives.

3. To lessen the danger of puerperal thrombosis, it is necessary to secure uterine contractions during the third stage of labor, and in the early hours of puerperium, even if no *post-partum* hemorrhage is threatened. This rule is especially imperative during the existence of epidemics of puerperal fever. Uterine contractions may be secured by massage of the abdomen and fundus, application of a binder, or the exhibition of ergot.

4. The lochial secretion must be regulated by complete rest in bed, absolute cleanliness, protection against cold, and careful ventilation of the room.

5. Puerperal ulcers of the genitals, caused by the irritant action of the lochial secretion upon the traumatic effects of labor, must be rendered proof against the resorption of pus, during the first eight days, by the local application of potassium permanganate, basic sesquichloride of iron, or tincture of iodine.

6. To arrest the fermentation process in the blood, or to limit its pernicious tendencies, five to fifteen grains of quinine may be exhibited daily with advantage. Axillary temperature of 39° C., pulse frequency of 100, dysphoria, constitute indications for the immediate use of the drug.

HOSPITAL NOTES.

ST. MICHAEL'S HOSPITAL, NEWARK, N. J.

(Service of DRS. WM. O'GORMAN and WM. PIERSON.)

SUBACUTE TETANUS COMPLICATING SCALDS (THIRD AND FOURTH DEGREES); RECOVERY.

Reported by ARTHUR C. DOUGHERTY, M.D., Surgical Clinical Assistant.

JOHN K., æt. 22; Ireland; laborer; admitted December 15, 1882. Patient is a strong, healthy man, of slight build; habits temperate.

On December 5, 1882, while on night duty at a bone-dust manufactory in this city, the patient, while endeavoring to pass between two large pans of boiling ammonia, slipped, falling partly into one of the pans. At the time of the accident the patient wore a pair of rubber boots, by means of which his feet were protected. During the ten days which intervened from the time of the accident until his admission into the hospital, the patient was treated at his home, the treatment consisting of the external application of carron oil and internal administration of morphine.

Admitted December 15th. Condition on the morning of December 16th: on the right lower extremity, halfway up the thigh, and for the same extent down the leg, patient presents a scalded surface; the burns varying from the third to the fourth degrees. Also a smaller scalded surface of the third degree in the right inguinal region, and severe scalds of third and fourth degrees on right and left arms and forearms. The sloughs were beginning to separate. The patient's tongue was brown and dry, pulse 124 and feeble, and during the preceding night he had been so delirious as to require to be strapped in bed. He was ordered liq. morph. sulph., U. S., ʒij p. r. n., and the liberal administration of milk punch. The local measures were emollient and protective. From that time the patient's condition continued to improve, his temperature gradually falling and his pulse becoming slower and stronger, until the morning of December 23d (the eighteenth day after the accident), when the patient, after having passed a comfortable night, noticed a slight stiffness of the jaws. He said that he remembered having had a slight jerking o his jaws when about half asleep. This symptom,

however, was so trivial that he attributed it to an uncomfortable position of his neck in bed. He had "no sore throat," and no stiffness of the post-cervical muscles. Tetanus being suspected, the patient was ordered large doses of potassium bromide and chloral hydrate. On the following day the jaws were almost locked, and in addition he was ordered pulv. morphiæ sulph., one-fourth of a grain every two hours. As yet the act of swallowing occasioned no clonic spasm, and the nourishment was introduced through the aperture left by an extracted tooth. His temperature and pulse now both began to rise, his tongue again to become dry and brown, although his rest at night appears to have been pretty fair. His temperature continued to rise for four days, at the end of which time it again began to sink toward the normal.

His condition was now as follows: jaws firmly locked, and slight tension of left sterno-mastoid, masseter, and rectus abdominis muscles; pulse 121 and feeble, and tongue dry. The tonic spasms now continued to become more marked, and at the end of six days a condition of pleurosthotonos toward the left side was well developed. The patient was now ordered morph. sulph., gr. j every hour in suppository. During this time the patient continued hopeful, and during the day his mind was clear. Clonic spasms had now and then been present, but until the eleventh day from the beginning of the attack they did not form a prominent symptom. They then became more frequent, being brought on by the act of swallowing, or by touching the patient. In this condition the patient continued for two days, when the clonic spasms began to come on less frequently, and the tonic spasms to relax. During this time the patient obtained some sleep at night, and was able to take nourishment in small quantities. On the seventeenth day the contracted muscles began appreciably to relax, except those of the jaws, which, ten days later, had only relaxed so as to allow the patient to open his mouth one-half an inch. He was now getting about gr. vj of morphine during the twenty-four hours, and in spite of the large amount of the drug he had taken at different times, he did not once exhibit the signs of opium narcosis. He now continued to improve until his discharge, the clonic spasms first disappearing, and after these the tonic spasm, which, however, persisted in slight degree for two weeks or more after the disappearance of the former. As the patient improved, bromide of potassium and chloral were substituted for the morphine. He now ate and slept well, having a famous appetite, and on January 31st (thirty-nine days from the beginning of the attack), as I made my rounds of the wards, the patient was dressed and eating his dinner, in a chair. On February 9th the patient was discharged, cured, his being the fourth case of recovery from tetanus in the history of the hospital. His burns had healed, and attempts had been made to lessen cicatricial contraction as much as possible by passive motion.

Remarks.—This case is interesting from the length of time (eighteen days) which intervened between the receipt of the injury and the first appearance of the lock-jaw, at which time the burns were granulating nicely, and the patient's general condition daily improving. That, throughout the attack, with the exception of two days, the tonic spasms predominated over the clonic, and, finally, as an example of the most surprising vital endurance, for the burns themselves were of such severity as apparently to preclude any but the most unfavorable prognosis. This patient noticed, as he began the second time to improve and to regain the power of swallowing, that hot liquids (as warm milk) taken by the mouth, had a greater tendency to bring on muscular twitchings than the same liquids in a cold state.

MEDICAL PROGRESS.

An Undescribed Disease of the Fallopian Tubes.—At the meeting of the Obstetrical Society of London, on November 7th, Mr. Lawson Tait contributed the following case. The patient, aged thirty-six, suffered from constant pelvic pain, aggravated during menstruation and after sexual intercourse, and was much emaciated and haggard. She had had much fruitless medical treatment. There were no physical signs of pelvic disease, except great tenderness. Mr. Tait made an exploratory incision, and found the fimbriæ of the tubes adherent by curious little nodules like millet-seeds. He therefore removed the uterine appendages, with the result of completely restoring the patient to health. The nodules had been examined by Mr. F. S. Eve, who reported that he could offer no opinion as to their origin or nature, but that they were neither cartilage nor bone. —*Med. Times and Gaz.*, Dec. 1, 1883.

Resection of the Œsophagus.—This operation was performed on September 23d, at the Ospitale S. Giovanni in Turin, for epithelioma.

The patient was a woman æt. 45. One year ago she began to have symptoms of stenosis of the œsophagus, and when she came to the hospital she was much emaciated from an inability to take food. The stenosis was so great that no œsophageal sound could be passed. Dr. Novaro diagnosticated epithelioma of the œsophagus, and performed Czerny's operation for resection. Having cut through the superficial tissues and exposed the œsophagus, a guide was passed into the mouth, and the seat and extent of the tumor easily made out. Having then separated the œsophagus from the trachea, and fixed it with silk stitches, he made a transverse resection about four-fifths of an inch below the lower limit of the tumor. The upper portion to be resected was two and four-fifths inches long, and involved a portion of the pharyngeal wall. It was also necessary to remove the posterior arytenoid muscles. Symptoms of asphyxia coming on, tracheotomy was performed. Through the opening in the gullet an œsophageal sound was slipped in, and after a week, was placed permanently through the mouth. A month after the operation there was an œsophageal fistula one inch and two-tenths long, for which a plastic operation was performed by Hüter's method for tracheal fistula. The tracheal tube and œsophageal sound have not been removed, and so far the operation has been successful.—*Gaz. degli Ospitali*, December 9, 1883.

Glycerine in Acute Fevers.—Professor Semmola calls attention to the use of glycerine as an aliment of economy in the treatment of grave acute febrile processes, and especially in typhoid fever. Alcoholic drinks, he says, have only a pretended antiseptic action, which has deceived many eminent practitioners. In his

opinion, alcohol produces a toxic action very much as do other antipyretics—veratrine, digitalis, carbolic acid, and salicylic acid—disproving the dangerous utopian ideas of some young physicians concerning the power of carbolic and salicylic acids, etc., to cure or abort typhoid fever.

As to alcohol, on account of its exciting action on the heart and cerebrum, and its disturbing action on the digestive organs, Semmola has entirely discontinued its regular and constant use as an aliment in grave febrile processes, reserving this agent for combating threatening heart failure.

Glycerine, on account of its chemical composition, long since appeared to Semmola as a substance which might replace alcohol in these fevers, and which would give the patients a greater resistance to the action of the fevers. He uses the following formula:

℞.—Glycerine, pure, ... f℥j.
Citric or tartaric acid, . . . ℥j.
Water, ... ad. f℥xvj.—M.
S.—f℥v–viij every hour.

This solution is well borne by the patient; but sometimes, on account of its acidity, Semmola often gives it at the hours for taking milk or beef-tea. In the rare cases in which the solution is unpleasant to the patient, he replaces the acid by a few drops of oil of anise.

The principal therapeutic effect, and the only one upon which Prof. Semmola insists, consists in the quantity of urea eliminated. From an accurate observation of twenty cases of typhoid fever, he concludes that the diminution during twenty-four hours may amount to so much as ℥vij, and as a rule it is from grs. xc–c. He has proved by experiment that the glycerine is the causative agent in this diminution.—*Journal de Méd. de Paris*, December 22, 1883.

CONVALLARIA, CONVALLARIN, AND CONVALLAMARIN.—PROF. DR. E. MARAGLIANO has recently made further researches as to the action of these preparations—the watery and alcoholic extract of convallaria, and of convallarin and convallamarin—on the pulse-curve, pulse and respiration, and blood-pressure, and draws the following conclusions from his experiments:

1. The intra-arterial pressure, measured by means of Basch's apparatus, is never lowered, but is sometimes raised as much as twenty-five or thirty millimetres.

2. The pulse-curve is never depressed in the ascending lines, but a marked rise is sometimes observed.

3. The frequency of the pulse and respiration is generally diminished.

Other experiments as to the action of the different preparations of convallaria gave the following results:

1. The urinary secretion was often increased, sometimes very markedly. Convallamarin acted more powerfully, while convallarin and the extracts were less active.

2. The frequency of the pulse and respiration was either increased or remained unchanged.

3. The blood-pressure was not lowered; sometimes it was raised.

4. The pulse-curve was generally unchanged, though sometimes the systolic lines were higher.

5. During the treatment with convallaria preparations, no bad effects nor intolerance was observed, except a few cases of diarrhœa. Of the diseases in which the good effects of the convallaria preparations were observed, heart diseases, of which thirteen cases were observed, occupy the first place. It acted well in valvular diseases, especially of the mitral orifice, with insufficient activity of the cardiac muscle. In nine of the thirteen cases the preparations were decidedly advantageous. They increased the amount of urine, and regulated the heart's action. In many cases convallaria is preferable to digitalis. In four cases in which it failed, digitalis also failed. Convallamarin also acts most powerfully in cardiac disease.

The convallaria preparations do not give the good results in pleurisy with sero-fibrinous exudation which have been attributed to them. They are superior to digitalis, in that they produce none of the unpleasant effects of digitalis, and have not its cumulative action.—*Centralbl. f. d. med. Wissensch.*, Oct. 27, 1883.

CASTRATION IN THE FEMALE.—TAUFFER is very favorably disposed to this operation. After having reported twelve cases, he concludes:

1. With necessary precautions this operation is not very dangerous; the mortality being only ten per cent.

2. It should be done under the spray; the abdomen should be closed; drainage is only exceptionally necessary.

3. The fact that the woman is near the menopause is no contraindication, for we cannot positively say when the menses will cease.

4. It is impossible to give any rule for operating, such as Hegar's, that the ovaries should be accessible to palpation.

5. Double ovariotomy should be performed, especially when a single ovary is diseased, except in the rare cases where one of the organs must be preserved.

6. The Fallopian tubes should be removed if they are diseased in any way.

7. Hystero-epilepsy is curable by castration; and the group of symptoms known as hysteria is often attributable to ovarian disease.

8. The question as to the effect of the ligature of the large supplying vessels on uterine fibromyomata needs further consideration.

9. As to prognosis, it is probable that the menopause will not be delayed after the operation except in the cases in which inflammation has involved the neighboring organs. These inflammations retard the menopause.

10. It is desirable that the cases should be classified according to the plan suggested by Hegar.—*Ann. de Gynéc.*, December, 1883.

HYDATID OF BASE OF SKULL.—An interesting case of an obviously incomplete character was brought under the notice of the members of the Société Médicale des Hôpitaux, by M. Bucquoy, on November 23d. The subject of the disease exhibited well-marked atrophy with paralysis of the facial muscles, internal squint and anæsthesia, all on the left side of the face. There was no history of syphilis or of any other morbid antecedent. The malady had set in three years before with headache, and a tumor had made its appearance at the angle of the jaw in the beginning of the present year. Many hydatid vesicles had been ejected from the mouth. The tumor was opened by M. Bucquoy by an incision, and much

purulent fluid let out mixed with hydatid vesicles. The patient still had a fistula at the angle of the jaw (the site of the incision), from which hydatid vesicles continued to be discharged at intervals. The paralysis was persistent. M. Bucquoy thinks that the cyst involved the sphenoid bone and projected thence into the pharynx. The case itself excited some discussion. M. Dujardin-Beaumetz asked whether the hypothesis that hydatids still existed in the brain was excluded. Owing to the spastic state of the masticatory muscles, it appears that a careful examination of the pharynx was not possible. Whatever the probabilities, it is obvious that nothing short of actual inspection of all the parts concerned could be expected to clear up every point of interest in the case.—*Lancet*, December 8, 1883.

Quebracho, Aspidospermin, and Quebrachin.—Maragliano gives the following as the results of his experiments on the action of these substances:

1. The alcoholic extract of quebracho, quebrachin, and aspidospermin have a diminishing action on the frequency of respiration, aspidospermin being the least powerful.

2. These substances act only when the increased frequency of respiration depends, not on affections of organic or mechanical nature, but on functional disturbances. In acute and chronic cardiac and respiratory diseases, they are of value; but they have no marked action on the frequency of respiration if this oversteps the physiological limits.

3. These substances, quebrachin and aspidospermin especially, have a decided influence on the pulse-rate, which may be diminished so much as twenty per minute.

4. The action of quebrachin and aspidospermin on the intra-arterial blood-pressure, with Basch's sphygmomanometer, is entirely negative.

5. The action of these substances, especially quebrachin and aspidospermin, is very quickly manifested: if given per orem, in from thirty to forty minutes: if hypodermatically, in from five to ten minutes. In giving the alcoholic extract no symptoms of intolerance have been observed. Sulphate and hydrochlorate of quebrachin and aspidospermin were administered in pills containing gr. ¼–jss each, the daily dose being gr. iij¾–xv.

Large doses cause gastric troubles. A medium dose is gr. vj–vijss taken internally during the day. For hypodermatic injection, quebrachin and sulphate of aspidospermin should be used, gr. ¾–jss at each injection. When this amount is completely dissolved in water it causes no local or general unpleasant results, and a diminution of the respiration- and pulse-rate is soon observed. For asthmatic attacks, quebrachin, used hypodermatically, is to be preferred; but for methodical treatment, the alcoholic extract is preferable. These preparations, then, are important additions to the physician's armamentarium. The best preparations are manufactured by Merck, of Darmstadt.—*Centralbl. f. d. med. Wissensch.*, October 27, 1883.

Trephining for Syphilitic Exostosis.—M. Perrin reported this case to the Société de Chirurgie in June, 1883. The history is as follows: In 1854 a spent ball struck him on the forehead. This was followed by obstinate cephalalgia. In 1865 he contracted syphilis, and was treated with mercury; the cephalalgia persisted. In 1869, the pains in the head became more violent, and Nélaton removed five sequestra from the frontal bone, there having been a fistulous tract since 1854. In 1870, the cephalalgia reappeared, and was relieved by specific treatment. In 1875, he became very excitable, and lost his memory; had difficulty in articulating words, and there was incomplete facial paralysis of theleft side.

He entered Val-de-Grâce, when M. Perrin found a large projection in the frontal bone, having a fissure in the centre into which a stylet could be introduced, and from which pus flowed. The stylet could be carried towards the external orbital suture, and in a short time pus escaped through the nose. The symptoms became aggravated, and he was put on mercury and iodide of potassium.

M. Perrin then trephined the frontal, and found that the bone was less than three-fifths of an inch thick. Alcohol dressings were applied, and the wound rapidly healed. A month afterwards, the paralysis disappeared, and articulation was easy. A few months later, the patient was put on iodide of potassium in large doses, and mercurial frictions, since which time the health has been excellent.—*Ann. de Dermat. et Syphil.*, Nov. 1883.

Globulinuria in Acute Bright's Disease.—A case of acute nephritis is reported by Werner, of Heidelberg, as occurring in Prof. Dusch's clinic, which is probably unique. It was that of a child, aged five years and a half, who developed symptoms of the disease after exposure to wet five days before his admission into the hospital. There was only a little œdema of the eyelids, together with signs of diffuse bronchial catarrh on admission, but general dropsy rapidly supervened, and death occurred from suppression of urine five days afterwards. What renders the case remarkable was that the urine only contained globulin, and never serum-albumen, although repeatedly examined, amongst others by Kühne.* The characters of the urine were its high color, cloudiness, and moderate deposit, but no blood. Slight turbidity appeared on boiling with nitric acid, and also with acetic acid, clearing up, on excess; and after supersaturation with magnesian sulphate no precipitate was obtained in the filtrate on the addition of nitric acid. Fatty epithelial and granular casts were found. The writer points out that hitherto globulin has never been met with in urine unless in company with serum-albumen; and quotes the statement of Senator to the effect that the quantity of globulin is most in the amyloid form of renal disease, next most abundant in acute nephritis, and least in the chronic diffuse form, although much albuminuria may be present. The same author also suggested that the globulin may be derived not only from the blood, but also from the morbid changes undergone by the renal epithelium, and Herr Werner thinks his case proves the possibility of its being solely derived from the latter source. He interprets his case, then, as one in which the renal epithelium was principally affected, which speedily and widely fell into a necrotic condition, as evidenced by the tube-casts, and that this necrotic cell protoplasm was the source of the globulin. The idea is, to say the least, ingenious; and it is most unfortunate that no post-mortem examination was obtainable. It should be added that the child had previously been in good health, and had never had scarlet fever.—*Lancet*, December 8, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 26, 1884.

THE ELECTRIC LIGHT AND GAS-LIGHT COMPARED.

THE introduction of the electric light has not only supplied a superior means of artificial illumination, but it has stirred up a competition that has resulted in great improvements in other methods of lighting. It has also directed attention to the study of the connection between lighting and hygiene, which will lead to important results.

As the introduction of gas gave an impetus to the improvement of oil lamps, so has the new illuminant—electricity, by the competition it has aroused, brought out improvements in the methods of gas-lighting which are altogether unprecedented. It is said that there is as great a difference between the light given by gas-burners recently invented and that of those which were in use ten or fifteen years ago, as now exists between the electric light and the present means of illumination by gas. And it is not too much to expect that, with improved contrivances for the most perfect combustion, and for conveying its waste products to the external air, along with means for the utilization of the temperature of combustion for ventilating purposes, and the application of the incandescent principle, gas-light will be able to compete on favorable terms, even from a hygienic standpoint, with the electric light for indoor illumination. At present, however, the incandescent light *in vacuo* is hygienically beyond comparison with the ordinary gas-light.

The heat produced by the resistance of the delicate filament of carbon used in this form of the electric light is hardly appreciable, and is therefore not sufficient to have any effect upon the gases of the atmosphere. The light being *in vacuo*, there can be no possible vitiation of the air. Another advantage is its almost perfect accordance with the laws of visual hygiene, in that it permits of the selection of the different colors the same as by daylight.

The source of light in the new illuminant depends on the "energy of current electricity." With the older illuminants, it depends on the "energy of chemical affinity." Coal-gas has a great affinity for oxygen, and will ignite in its presence if the temperature be high enough. Its combustion cannot take place without the production of considerable heat, and the abstraction from the atmosphere of a large amount of oxygen. Moreover, the process is attended with the production of deleterious substances, the result of chemical combination.

The development of heat by the combustion of ordinary illuminating gas is not so much an objection, as this may be utilized for ventilating purposes; but the abstraction from the air of a large proportion of oxygen—the life-supporting element of the atmosphere—and the production of deleterious compounds, are the features which cause gas-light, as ordinarily used, to be injurious to health. According to Mr. Slater, every cubic foot of ordinary coal-gas, giving fifteen candles for five cubic feet per hour, requires for its perfect combustion 1.17 cubic feet of oxygen, so that in a room lighted for two hours by three good burners, the gas would require 35.1 cubic feet of oxygen.

The products of coal-gas combustion are mainly aqueous vapor, carbon monoxide, carbon dioxide, and sulphuric acid. Sulphuric acid is one of the products of oxidation of the carbon disulphide, traces of which are not uncommonly found in ordinary gas. This constituent makes its presence known by the damage it causes to plate, pictures, etc. When gas is imperfectly oxidized, a considerable quantity of carbonic oxide escapes into the air and forms a dangerous impurity. Carbon dioxide is the chief constituent of the products of gaseous combustion. The amount of this gas in normal air is, on an average, 0.04 per cent.; it frequently varies from this mean. Now it is evident that this standard cannot be maintained in a confined space where the combustion of gas takes place, unless special means are used for the removal of the products of such combustion and the fresh supply of pure air.

The freedom of the incandescent electric light from these serious disadvantages gives it a superiority over any means of artificial illumination hitherto invented, and causes it to rank as the hygienic light of the future. The convenience of gas as an illuminant is a strong influence in its favor, but this claim cannot be expected to be long withheld from its new rival. Attention will then, more than ever, be directed to the perfection of appliances for the

entire removal of the harmful products of combustion, the supply of fresh air to counterbalance the loss of oxygen, and to the improvement of the quality of the light by some such invention as the Siemens, Grimston, or Lewis incandescent gas-burner, so as to avoid the disadvantages of the system of coal-gas illumination, and at the same time to afford the maximum illuminating power with a quality every way satisfactory.

With regard to the electric arc lights, it is stated that, unless enclosed in air-tight globes, they produce nitrogen oxides from a rearrangement of the gaseous constituents of the atmosphere thrqugh the intense heat of the voltaic arc. Carbon dioxide is also said to be produced in the same way. The varying densities of the light from the heterogeneous character of the carbons cause muscular fatigue of the eyes and also render retinal images indistinct. From a sanitary standpoint this light cannot be said to be so satisfactory for indoor illumination as the incandescent light *in vacuo*.

THE PRACTICAL ASPECT OF THE BACILLUS TUBERCULOSIS.

The article by Prof. Flint, Sr., "On the Pathological and Practical Relations of the Doctrine of the Bacillus Tuberculosis," published in our last issue, is worthy of careful perusal by all readers. Dr. Flint's high position in connection with American medicine, as well as his long association with pulmonary diseases, make his opinion more than commonly valuable on this important subject.

Dr. Flint unequivocally accepts the doctrine that a micro-organism is one of the factors in the production of tubercular phthisis, that it is essential, and that there is no tubercle without it; while, on the other hand, he does not consider it alone sufficient to produce the disease. With it must be associated the second factor, predisposition, either hereditary or acquired. Whence it follows, too, that tuberculosis is an infectious disease in the sense in which this term is accepted to-day, viz., a disease dependent on special causative agents which, under favorable circumstances, are capable of multiplying indefinitely, either within or without the body. In that the bacillus requires a soil favorable to its development, a condition furnished by the predisposition, tuberculosis is not different from other infectious diseases.

Another conclusion accepted by Dr. Flint is that pulmonary phthisis, which we now again regard as a synonym for pulmonary tuberculosis, is primarily a local disease, the initial morbid process taking place in the lungs and being due to the presence of the parasite. The fact that no other infectious disease is local, even primarily, in the sense that tuberculosis is local, seems, to Dr. Flint, in no way to militate against its infectiousness. We do not know that it ought to be considered as doing so, but the fact itself should not be overlooked.

That clinical statistics fail to show that tuberculosis in man is contagious, is owing to the fact that in most cases the concurrent coöperating conditions embraced under the term predisposition are wanting. This view is further sustained by the fact that different animals differ widely in the susceptibility to tubercle inoculation, cats and dogs possessing comparative immunity, as compared with rabbits.

In the diagnosis of tubercular phthisis, Dr. Flint assigns the bacillus a high value, believing that if repeated, sufficiently careful examinations show its presence, phthisis is present, while its absence excludes the possibility of the disease.

The application of these new doctrines to the prevention and cure of phthisis, is admitted to have been thus far without practical results. The preventive measures now available are those available before the bacillus was known, and no measures have been discovered which can destroy the parasite without destroying the patient.

We hope the publication of Dr. Flint's paper will have the effect of attracting the attention of clinicians on this side of the Atlantic to this important subject. For, as yet, they have done very little for us in this direction. The profession in this country are sometimes even too ready to avail themselves of practical suggestions in the direction either of operations or therapeutics, involving little thought and labor, but they are still too unwilling to devote the time and labor required to work out such results. Dr. Flint's evident painstaking care in the preparation of his paper, notwithstanding his numerous engagements at this season, is certainly an example to us.

SHORTENING THE DURATION OF PREGNANCY.

Contributions to our medical literature are not unseldom made with the design of showing how the first stage of natural labor can be shortened, and the method almost invariably advised is dilating the os uteri by the fingers. It is true this method has been strongly condemned by many great obstetricians from Baudelocque to Barnes, the latter not many years ago speaking of it as "old and bad;" nevertheless it undergoes frequent revivals, its advocates presenting it if not as a new, at least as a very useful interference or assistance in normal labor. Undoubtedly any means that will lessen the suffering and avert the perils of childbirth ought to be received with favor, and while we do not propose to discuss this method, or any other having directly its design, at present, we wish to consider a more

important subject, viz., lessening the term of human pregnancy.

It must strike the thoughtful as strange that while science has done so much to relieve feathered domestic animals of the weariness, the emaciation, and the exhaustion of a few weeks' incubation, accomplishing by artificial heat in a day or two that which the clucking mother cannot do in less than three weeks, nothing has been done to shorten the long period of nine months during which the human mother carries on the internal incubation of her egg. Certainly every one will admit that it is desirable to relieve women in pregnancy of all the inconveniences and dangers their state brings. Now it must be conceded that usually these inconveniences and dangers are greatest in the last two months; and, like the western farmer who, observing that the squirrels only ate the corn in the outside rows, concluded he could save his field from their ravages by having no outside rows, so do not let the pregnancy have any last two months in which such dire evils may come.

It must also be obvious to the observant practitioner that childbearing is not the simple and safe process it was when the race was young. It is quite probable that in the intellectual development of mankind the head is bigger than heads once were, the maternal passage is not large enough for the passenger, and so uterine and vulvar orifices tear instead of stretch as they did in the good old times. Whether these lacerations, which furnish so important a field for the busy skill of those most accomplished and polished members of the medical fraternity known as gynecologists, are thus explained, or whether they result from an inferior stuff, a sort of somatic shoddy, put into woman's sexual apparatus, deficient in strength and elasticity, or from some other cause, certainly it is very sad to think that a woman cannot have a baby without subsequently in many cases having to be put in a repair-shop for a few weeks, or even months. No wonder many women shrink from childbearing, avoid it *per fas et nefas*, when babies cost so much. Formerly a midwife did all the work, and her fee was a trifle; but now the obstetrician attends in the labor, and after the ordinary period of puerperal convalescence, in one case of five or ten, is succeeded by the gynecologist. Again, adopting the wise apothegm of the late President Lincoln, a small debt is more easily paid than a large debt, will not a small baby be born sooner than a large one, and thus not only the first, but also the second stage of labor be shortened?

We think by these arguments we have clearly shown the desirability of shortening the duration of pregnancy, and the great blessings such abridgment would give.

It remains for us to consider some of the means that may be used for the accomplishment of this end. Why pregnancy ends at nine months is still an unanswered question, but we hope that the suggestions we make may lead to the final solution, for by trying various ways to bring on labor, we will find some one which is always certain, safest, and best, and, therefore, that may be accepted as Nature's way. Let us suppose, for example, that fatty degeneration of the decidua renders the ovum a foreign body, and thus the excitant of uterine contractions. Accepting this theory, we may give the woman arsenic or other steatogenous medicine, beginning a few weeks before we wish labor to occur. Or again, the Tyler Smith theory, that labor comes on from ovarian influence, is quite as probable as the one just mentioned; here our task is very simple, and its result ought to be certain: we depend altogether upon faradization of the ovaries, and if we continue this daily for a sufficient length of time, labor will surely come on. But possibly the exciting cause of labor is the excessive distention of the uterus. In these days, when resection of the stomach and pericardial paracentesis are so successfully done, there ought to be no hesitation as to introducing a canula into the fœtal sac, and pumping in a sufficient quantity of warm water to excite uterine action; it is possible that labor could be thus induced within a few hours, and as the most important means of this induction is a syringe, the peculiar fitness of Uncle Toby's question, "Are children born with a squirt?" would be plain. And thus we might show that there is not a single theory of the determining cause of labor which cannot be illustrated by artificial means.

But some philoprogenitive friend may ask whether these babies thus coming at seven months will not be so feeble that they cannot live. Most assuredly they can and will live, for that admirable invention, the *couveuse*, which, of course, is not to be confounded with a caboose, though each is remarkable for its warmth, is just adapted to such infants. Read Auvard's paper in the October number of the *Archives of Tocologie*, an abstract of which appeared in last week's issue of THE NEWS, and it will be seen that babies considerably under seven months get on very well by the help of the *couveuse*. Apart from any modern facts showing that seven months' babies do live and grow to healthy maturity, we have, in the nineteenth book of the *Iliad*, the case of Sthenelus's wife, "scarce seven moons gone," lacking, therefore, somewhat less than three lunar months the completion of pregnancy, who gave birth to a healthy son, and that son was especially favored according to Jupiter's promise.

Of course, we do not expect our suggestion as to shortening the period of pregnancy to be at

once accepted; an important idea of this kind can only gradually make its way. But when the practice is adopted, let there be no dispute as to with whom and when it originated. Alas! we do not know who first practised digital dilatation for the shortening of the first stage of labor any more than we know what song the Syrens sang, but all must know the importance of the suggestion now made by THE NEWS.

EMBOLISM OF THE SUPERIOR MESENTERIC ARTERY—PERFORATION OF THE INTESTINE.

AN interesting case of this rare accident is communicated by CONTI to the *Gazetta degli Ospitali*, 1883, No. 57. A man sixty-five years old was admitted to hospital with cerebro-spinal meningitis. Recovering from this disease, he remained two years on account of general atheroma of the blood-vessels. On January 19th, he became suddenly ill and died with symptoms of acute peritonitis. The autopsy revealed thickening of the pia mater of the convexity, moderate hypertrophy of the left heart, extensive atheromatous endarteritis, with numerous lateral thrombi of the ascending and descending aorta. The peritoneum was dotted with numerous hemorrhages, and in the middle third of the transverse colon was found a round opening, 0.4 of an inch in diameter, surrounded by a hemorrhagic areola. In the right half of the transverse colon were two larger subserous hemorrhages, while the mucous membrane of the colon and small intestine was œdematous. The entire large intestine was dilated, the muscular coat was hypertrophied in its lower part, and just above the anus was a cicatricial stricture covered with numerous polypoid vegetations and hemorrhoidal nodules. The entire superior mesenteric artery was occupied by a gray coagulum. The kidneys were granular.

It would appear from this that the superior mesenteric is a terminal artery and that embolism of it produces hemorrhagic infarct. In this case necrosis of the intestinal wall and perforation of the gut were superadded to the lesions.

"TERRIBLE TRACTORATION."

APROPOS of metallotherapy, we note that Perkins's tractors, at one time the most successful imposture then current, accomplished results not wholly explicable by the influence of the imagination. The effects of metals, or metallotherapy, are now generally acknowledged, and by those most competent to form a correct opinion. Perkins's tractors must have had curative effects, also, composed as they were of several metals. Beside the action of the metals, the mystical powers ascribed to the instrument were not without effect on the imagination. The wooden tractors used by Dr. Haygarth, of Bath, England, no doubt, accomplished as much as the genuine tractors in the treatment of affections having their seat in a disordered imagination. So, in our day, wooden images of genuine coins may have an effect not unlike that produced by the real metals. All imitations fall short, however, of the curative actions effected by the genuine tractors and metals.

In a former issue we called the attention of our readers to the Perkins's tractors as the real origin of that system of therapeutics now known as metallotherapy, or Burqism. The tractors excited an immense enthusiasm in England, and a Perkinsan Institute was founded in London for the benefit of the poor. The method was strongly opposed by the medical profession, ridiculed in the most unsparing manner, and denounced as arrant imposture. Haygarth's imitation tractors were asserted to produce the same effects as the genuine. At this juncture a powerful advocate of the tractors appeared in London under the title "Terrible Tractoration."[1] In this Hudibrastic poem all the medical novelties of the day are held up to ridicule, and the tractors defended. As a specimen of Dr. Caustic's wit we quote the following stanza:

> "Pursue the steps the learned sage hath,
> The most redoubted Doctor Haygarth,
> Who erst o'er Perkins's sconce at Bath,
> Broke a whole gallypot of wrath!!"

Terrible Tractoration was written by Thomas Green Fessenden, of Walpole, New Hampshire. He graduated at Dartmouth in 1796, was educated as a lawyer, but his tastes were literary, and he subsequently became a writer on agricultural matters. The poem above referred to betrays an extensive acquaintance with medical notions of the time. It was first published in England, where its author was engaged at the time, and an American edition appeared in 1804, in New York.

LUXATIONS OCCURRING DURING THE COURSE OF GRAVE FEVERS.

APROPOS of our editorial comments upon pathological luxations in the issue of THE NEWS for January 12th, our attention has been called to the Toner Lecture on the Surgical Complications and Sequels of the Continued Fevers, delivered by DR. W. W. KEEN, in 1877, in which that gentleman collected a number of examples of similar lesions confirmatory of the conclusions arrived at by Verneuil.

Of the 27 dislocations of the hip, 21 were spontaneous, and 6 were due to slight traumatism. In

[1] Terrible Tractoration!! A poetical petition against Galvanizing Trumpery and the Perkinistic Institution, in Four Cantos. Most respectfully addressed to the Royal College of Physicians, by Christopher Caustic, M.D., LL.D., ASS, etc.

all of the cases it is probable that the head of the femur rested upon the dorsum of the ilium, and in three the lesion was double. In 15 the accident occurred during the course of typhoid fever, and in 7 during the course of typhus fever, and 21, out of the 23 in which the age is noted, were under twenty years. In the remainder, the dislocation occurred twice at the shoulder, and once at the knee.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 17, 1884.

THE PRESIDENT, FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

DR. R. F. WEIR read a paper entitled

HOW ANTISEPTICS ARE USED IN THE NEW YORK HOSPITAL—A DEMONSTRATION.

After devoting some remarks to the antiseptics of the past and the manner of their use, he went on to say that one serious objection to both carbolic acid and iodoform was their highly poisonous character, and that medical literature now teemed with cases of fatal results attending their use. What quantity of carbolic acid could be employed with safety had not been definitely determined, but it had been demonstrated that it was dangerous to use more than forty-five grains of iodoform about a wound. Not quite two years ago (in March, 1882), Dr. Weir said he first began to employ bichloride of mercury as an antiseptic. All that he knew about the agent in this connection was derived from Delacroix's paper, and he at first used it in a very imperfect manner. After the researches of Kimmel, Koch, and others had been published, however, a clear idea of its powers and applicability could be obtained. It was now commonly employed in the proportions of one part to one thousand and one to two thousand of water, and it was a great boon to the surgeon to have a germicide that was both safe and cheap as well as efficient. Up to within a week he had believed that the solution of the bichloride was a durable compound, and that the acme of a surgical dressing had at last been reached. During the last few days, however, he had ascertained that it was not so durable as he had supposed; having determined to test this special point before appearing before the Academy on the present occasion. He had previously noticed that the solution when kept for some time became milky in appearance; showing that calomel had been formed at the expense of the bichloride. He had not, however, supposed that the same change took place in surgical dressings after having been put on; but he now found that after they had been in position from one to two weeks, the application to them of lime-water showed the black spot characteristic of calomel under this test, instead of the reddish tint yielded by bichloride of mercury. As soon as he discovered this, he wrote to Prof. Gibbs, of Harvard, and he had just received a letter from the latter in which he said that he thought that probably by the addition of a small quantity of common salt (five parts to a thousand) the solution might be rendered permanent, or at least more durable. At the same time he promised to make further investigations in regard to the matter.

The bichloride solution was used in various ways in the New York Hospital. In the dressing of wounds gauze or cheese-cloth was employed which had been impregnated with it, and the material used in this hospital, which cost only four cents a yard, was manufactured for it in such a way as to contain no sizing. Where the sizing existed it was necessary to get rid of it before using the gauze; which could be done by washing it with a weak solution of muriatic acid. The standard solution used at the hospital, was made up of 20 parts of bichloride of mercury, 44,480 parts of water, and 500 parts of glycerine, which is a one-quarter per cent. solution. In certain cases a stronger solution (one to one thousand) was employed. The advantage of the glycerine was that it prevented the dressing from entirely drying after it had been applied, as it had been found that the gauze became a little weakened by completely drying. In addition to gauze, various other substances were used for dressing, such as cotton, jute, peat, wood-pulp, and moss, and Dr. Weir exhibited examples of these in succession.

Peat, he said, was the most absorbent, taking up sixteen and a half times its weight of water, and also the cheapest, costing six cents a pound. Two varieties, the dark and the light-colored, were used, and sometimes these were mixed together. All that had thus far been employed had been imported from North Germany, but he had no doubt that it could easily be obtained in this country. Wood-pulp, which was used largely in Germany for manufacturing paper, was slightly more expensive, costing eight cents a pound, but it absorbed pretty nearly as much water, and it had the decided advantage over peat of being perfectly clean. But of all the substances which he had seen used in the European hospitals in a recent trip abroad, nothing pleased him so much as the bleached and pressed jute, finely carded, which differed very greatly from the common jute which most were familiar with. This costs forty cents a pound, but there was a good deal more bulk of it to the pound than of the other substances mentioned, and it was so soft and pleasant to the touch that it seemed to him the ideal surgical dressing. It did not, however, absorb as much water as the others. It could be obtained of M. Lienau, 2 Jones's Lane, New York, by whom it was imported. Another substance which served a very good purpose, and which could be found in any quantity here, was the ordinary moss of the woods. It would absorb from four to six parts of water, and it cost almost nothing. In the few instances in which he had employed it, Dr. Weir said it had answered very well.

In operations, he was accustomed to wash first the parts adjacent to the seat of trouble with a solution of two ounces of turpentine—which had been proved to be a good antiseptic—in a pint of alcohol. This was sometimes done the day before, and sometimes on the day of, the operation. Being a good solvent for fatty substances, it was very useful in removing any accretions from discharges.

In performing amputations, he now made use of a protector (a rubber cloth with a hole in it, through which the limb to be amputated was slipped), which he had seen employed in the hospitals in Germany. There

the surgeons were in the habit of keeping the part that was being operated upon constantly irrigated in a very free manner with antiseptic fluid, and such a device was necessary for the protection of the rest of the patient's body. In regard to the spray, he remarked incidentally that he had abandoned it, except in operations upon the joints and in the thoracic and abdominal cavities, in which he still continued to use it. He then digressed for a moment, to mention the antiseptic knives which Esmarch had devised. They are made of one piece of steel, so as to afford no lodgement for septic germs, which might possibly adhere to ordinary knives. One objection to them was that the handles were liable to become quite slippery if wet with blood, and in order to obviate this, Tiemann, of New York, had made some knives of which the handles were of baked rubber, but contained no crevices whatever. He also exhibited a variety of the latest hæmostatic forceps now in use, devised by Spencer Wells, Tait, Esmarch, and others, and said that he though the best was that of Hahn, of Berlin.

The amputation having been performed, all hemorrhage was to be arrested as promptly as possible; though if the Esmarch bandage had been properly applied, there would probably be none. For the tying of vessels, he had now given up the carbolized catgut ligature of Lister, which, while it was quite strong, was very slippery, on account of the olive oil used in the carbolic acid solution in which it was dipped. It had received a very severe blow, also, when Koch declared that carbolic acid when mixed with olive oil lost all its antiseptic qualities. Lister's chromic acid ligature was not open to the same objections; but the trouble with this was that it lasted too long, and thus constituted a foreign body in the wound. He therefore employed a catgut ligature prepared with bichloride of mercury solution, which, when dry, was devoid of slipperiness, and which was also sufficiently strong. It was first dipped in a solution of the strength of 1 to 100 for ten minutes, and then put in one of the strength of 1 to 1000 where it was allowed to remain for twelve hours; after which it was wound on a bobbin, and placed in 95 per cent. alcohol. An even better ligature was that which was prepared by dipping first in oil of juniper and then in alcohol, for the reason that it was not so brittle; and it was still better if it was kept in oil of juniper.

The wound was closed with the continued, instead of the interrupted suture (catgut being employed for the purpose); but an opening was always left at each end for the insertion of a drainage-tube. The black rubber tube was that which was commonly employed; but it was somewhat objectionable, because if left in position for longer than from three to five days, it caused an open tract, which required a considerable time to heal up. On the other hand, if it was removed early, it necessitated the renewing of the whole dressing, which was often very undesirable. To meet these objections, decalcified bone tubes had been devised by the German surgeons, and, as these become at length entirely dissolved, they answered a very good purpose. After the drainage-tubes had been passed in, the wound was flushed with corrosive sublimate solution until the latter came away quite clear, and compresses of antiseptic gauze were then fastened on the wound with sufficient tightness to keep up a moderate amount of pressure. Over the gauze was placed the absorbent cushion, the material composing which, whatever substance might be selected, was tacked in, so as to keep it of uniform thickness; and around the whole was wound the crinoline bandage. The stump, as dressed with the amputation cushion, presented somewhat the shape of a swollen turnip.

In many instances, an amputation was expected to heal under one or two dressings; and it was an understood fact that a cure was invariably more or less hastened by this manner of dressing. All this, of course, presupposed perfect cleanliness; and in the opinion of some authorities, it was in this point that the real secret of the success of antiseptic surgery lay. Tait, who had achieved such extraordinary success in abdominal surgery, was the apostle of cleanliness, and had discarded Listerism. His operating-room was the cleanest place that Dr. Weir had ever seen, and his instruments were all kept under water. He was particularly struck with the care that was taken with the sponges used, as he believed that more risks came from bad sponges than from any other cause. They were first thoroughly soaked with pure water, and then with a solution of one pound of soda to four gallons of water; after which they were soaked in pure water again, and then treated with carbolic acid, 1 to 20. In his wards, at the time that Dr. Weir visited him, were a number of cases of ovariotomy, hysterectomy, and other serious operations, and they were all doing perfectly well. In some there was a considerable increase of temperature, but it did not appear to occasion any apprehension on the part of Mr. Tait. The only thing of which there was to complain were one or two stitch-hole abscesses, such as were not observed in the cases of surgeons who practised the antiseptic method. Keith, of Edinburgh, rejected only the use of the spray in his operations, and Dr. Weir remarked incidentally that some surgeons, instead of the spray, made use, during their operations, of a boro-salicylic acid solution, with which they kept the parts constantly bathed.

In regard to sponges, it was very important to know how to prepare them for use, and to cleanse them thoroughly afterward, in case they were to be used again. At the present time, however, they could be purchased so cheaply that it was much better to throw them away after using them once. In the New York Hospital, the sponges are first hammered, so as to get the sand out of them, and then put in warm water. If the water was too hot, it would cause deterioration. They were then left in a 1 to 1000 solution of permanganate of potassa for twenty-four hours, and after having then been rinsed out in warm water, they were treated with a solution of 1 part of sulphite of sodium to 100 of water; one-fifth part of a solution of chlorhydric or oxalic acid (eight to one hundred) having first been added to the water. They are stirred up with a stick for a few minutes, until they whiten; if left longer, they will become friable. They are next washed out and placed in running water for some time, and finally in a solution of carbolic acid, 1 to 20, or bichloride of mercury, 1 to 1000. If the operation in which they were employed was about the abdomen, vagina, or rectum, they were thrown away immediately; but otherwise they were kept, and cleansed by the same process as before.

Dr. Weir then exhibited a splint, for compound fractures and other injuries of the leg, which was composed

of enamelled tin, so that the discharges from one patient could not possibly affect another using the splint afterwards.

In conclusion, he gave some statistics showing the great improvement in mortality since antiseptic surgery has come into vogue. Before antiseptics were employed the mortality from compound fractures in St. Luke's and the Roosevelt Hospitals was thirty-three per cent.; in the old New York, sixty per cent.; and in the Boston City Hospital, forty-one per cent. In Dr. Weir's hands, when the open method was used in the treatment of compound fractures, the mortality was twenty-six per cent., but since he had used antiseptics it had been only six per cent., and some other surgeons had achieved even more favorable results. He then gave some figures showing the same happy results in amputations performed after the antiseptic method, and brought his remarks to an end by saying that on account of the vast saving of human life by the carrying out of the principles which he first enunciated, the name of Joseph Lister deserved to be placed above all in the present century, not even excepting the discoverer of anæsthesia.

Dr. Post, in opening the discussion, said that he was fully convinced of the very great value of antiseptics in surgery, although he was perhaps not altogether prepared to adopt all the minute details that had been recommended. In unimportant cases, where there was little danger, he thought this would only cause unnecessary trouble, and believed that the securing of cleanliness and drainage would be sufficient. There was one antiseptic agent to which Dr. Weir had not alluded, but which he had found very efficient, and that was subnitrate of bismuth. When first recommended in this connection it was employed in the form of a solution; but recently he had used it in the dry powder, and he had found that wounds sprinkled with it did remarkably well.

Dr. Bryant said that he had watched the progress of antiseptics with a great degree of interest ever since 1868. While an interne of Bellevue Hospital, from the fall of 1869 to the spring of 1871, he had treated some twelve cases of compound fracture, and had thoroughly injected the wounds with carbolic acid solution of the strength of one to eighty, which was the strongest then employed; the ordinary solution used in the house being one to one hundred and twenty. The whole limb was also washed with the carbolic solution, and it was then surrounded with oakum and placed in a plaster-of-Paris splint. Of the twelve cases all but two recovered, and one of these was an exceedingly bad one. Since leaving the hospital, he had habitually used the ordinary Lister dressing, and recently in the place of carbolic acid had used bichloride of mercury solution in the strength of one to two thousand, in connection with iodoform, Lister gauze, peat, etc. He always got good results with the antiseptic treatment unless, as occasionally happened, there was some defect in applying the dressings. The methods in vogue at the present day could hardly be attributed to any one individual, though to Lister more credit was due than to any other. As a Bellevue surgeon, he could testify to the extraordinary benefits of antiseptics; and he then proceeded to mention some cases illustrating their advantages which had lately been under his care in the wards of that institution.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 19, 1883.

The President, Wm. M. Welch, M.D., in the Chair.

Dr. Roberts Bartholow read a paper entitled

WHAT IS MEANT BY NERVOUS PROSTRATION?

The popular conception of the condition now known as "nervous prostration," he said, is a state of debility in which nervous derangements predominate. A man actively engaged in business or in public life presently finds himself unequal to his daily tasks: he suffers odd sensations in his head; his digestion is disordered; he is weak; wakefulness, mental depression, and a thousand and one new sensations of strange character and fearful portent are superadded. The unfortunate subject of these ills now recoils from his work, gives himself up to the consideration of his symptoms, and relaxes his hold on the interests and occupations of his life. All the world declares that he has "nervous prostration," and this explanation satisfies. Physicians say "neurasthenia" or "hypochondria," according to their habits of mind or to their training. Sometimes this condition is called the "American Disease."

The term *neurasthenia*, advocated by the late Dr. Beard, is by no means of recent origin. The corresponding French word, used in the same sense as we now employ it, has been a stock-word of French neurological medicine for fifty years. Under the terms spinal irritation, hysteria, hypochondriasis, the nervous state, etc., symptoms of the same character as those now included in the word neurasthenia have been described. Besides the general state, similar derangements of functions of particular organs have been separately considered, as palpitation of the heart, headache, flatulence, impotence, etc. In the word neurasthenia—popularly, nervous prostration—the whole morbid complexus is included. The question I have to consider is whether this is a real, a substantive disorder. Are the notions now generally entertained about it founded on a true conception of the condition?

I need not enlarge on the importance of a correct understanding of a morbid state, which is supposed to be due to the conditions of modern, especially of American life. Dr. Bartholow then narrated the clinical history of two cases, representatives of the two types of neurasthenia, respectively the *congestive* and the *anæmic* varieties. The latter are greatly more numerous, but the former are not uncommon.

The causes of neurasthenia are complex; the effects are not limited to one organ, or set of organs, but involve the system in general. To name this malady from the disturbance in one system seems an error, unless the definition is sufficiently elastic to include all the functions affected. Neurasthenia names one, only, of the parts involved. There are two factors supposed to be especially influential in this country—work, and our exciting political and social life. I believe that the effect of these is greatly overrated.

The brain, of all the organs of the body, illustrates, in the most perfect manner, that which has been happily styled "the principle of least action." That is, to execute given tasks, it expends the least possible force, or, to express the same idea in another form, its work is

done with ease, with the minimum of effort. Given a certain amount of repose—sleep—and supplied with proper nutriment—healthy blood—the brain will do its allotted work continuously during its working—the waking—hours. So far from being injured by severe labor carried on under normal conditions, the brain is improved by it. Mental activity, like muscular exercise, keeps the brain in a healthy state. When, therefore, a man says he is suffering from the effects of mental overwork, I want to know what his vices are. Worry may be one of these. The ease and luxury of our American life another. It is the indulgence in eating and drinking, the abuse of alcohol and tobacco, sexual excesses, sedentary habits, and too luxurious lives generally, that induce the state of the system called nervous exhaustion.

Why are the somatic derangements caused by the conditions referred to, in some cases accompanied by the mental and nervous symptoms which belong to neurasthenia? Why do some subjects with indigestion and assimilative disorders, or with the results of dyspepsia and malaria, suffer from the derangements of the mental and nervous functions, and not others. I might here take refuge behind an accepted generalization, and say that the presence or absence of the neurotic type of constitution explained the difference in the result. There is aptness in this explanation, but it is not entirely adequate. There is a mental condition of great importance, and unless we comprehend this, we fail to realize all the possibilities of the nervous side of these cases. I, however, barely hint at the main points, under these circumstances. Besides, I wish to avoid a too metaphysical discussion of the subject.

In the conduct of life every man who has a position to make or to maintain, exerts a certain moral force to hold himself up to his work. Some men are so happily constituted that they are quite unconscious of the effort and stand in the front, serenely confident. Others are all the time laboring; they feel it and know it, and like the soldiers of Thomas's corps at the battle of Chickamauga, sorely pressed, now and then look back, to see whether their grim and resolute commander was still behind them with his invincible courage. Men conscious of the effort making to keep up, need but little excuse to surrender themselves to their sensations. At the present time nervous prostration is much feared; its symptomatology is a common subject of discussion; and hence, familiar with its character, a man who is arrested in his career by some of the ailments supposed to belong to it, his imagination readily supplies the rest. When a man begins the study of his bodily sensations, having a certain model in his mind, he has little difficulty in filling out the details. All the world knows that when the attention is strongly fixed on an organ of the body, functional disturbances of it ensue, and finally structural changes may be induced. No part of the body is without sensation, even in health. To perceive these sensations the attention needs to be withdrawn from external things, and concentrated on the part. Thus it is when the subject of neurasthenia pursues his introspection, he becomes conscious of numerous sensations, which, because now felt for the first time, are new. Under these circumstances, also, the seat of conscious impressions becomes more acutely perceptive. Suggestion adds its quota of symptoms.

To the indefinite and multiplying nervous symptoms developing thus subjectively, must be added the reflex. Headache, vertigo, *tinnitus aurium*, amaurosis, diplopia, hallucinations and illusions, defects of speech, paralysis, are reflex symptoms on the part of the brain; palpitation, intermittent pulse, angina pectoris, laryngismus stridulus, asthma, are amongst the reflexes of the respiratory organs and heart; neuralgia, anæsthesia, and other disorders of the sensory nerves, and local paralyses, affections of the motor nerves, included amongst the nerve reflexes, may all be dependent on reflex excitations proceeding from the stomach. Indeed, there is no symptom in Beard's catalogue of those belonging to neurasthenia that may not be due to merely reflex influences having their initial seat in the digestive apparatus. It follows that the term neurasthenia, or its common equivalent, nervous prostration, is either inadequate, or it expresses too much. Inadequate if the complex of symptoms includes the functional disturbances of all the organs affected; expresses too much if the malady is a merely nervous one.

In reply to the question, "What is meant by nervous prostration?" I respond: A disease usually functional, situated in one or more organs, during the course of which reflex disturbances of the brain occur, and numerous subjective sensations in all parts of the body are realized by the consciousness. I deny that neurasthenia is a primary nervous affection, or that it is a substantive disease. I hold that it is symptomatic and secondary.

This conception fixed in the mind, the treatment of neurasthenia is successful or unsuccessful according to the measure of our skill in localizing the initial disturbance, and in addressing our remedies to that as well as to the general state.

DR. MILLS, in opening the discussion, by request of the Chair, said: I understand that Dr. Bartholow denies that a disease exists, primarily nervous in origin, which can be called neurasthenia. He classes all cases so-called under two heads, congestive and anæmic, and holds that the symptoms presented are chiefly reflex effects of digestive or other visceral troubles. I have no doubt that many cases are to be thus explained, but we have others in which the cerebral condition is primary. In cases with the symptoms as detailed in the paper, we may perhaps clearly ascribe them to the causes and conditions referred to by Dr. Bartholow, but other cases may be explained in a different manner.

In individuals whose higher ganglionic centres are so constituted, from bad inheritance or poor training, or both, that they cannot bear much strain, when subjected to this strain these centres exhaust. We have certain functions called organic functions, respiration, vasomotor action, etc., with centres in medulla oblongata and spinal cord. These functions must be maintained as long as the individual exists. Their centres must be nourished and sustained in a uniform way. Presiding over automatic movements, they must be kept in the highest tone, must have good blood and plenty of it. It is a principle brought out in the paper that local diversion of blood to any one organ or part will take it from other organs or parts; and we may, in accordance with this, have the higher brain diverting blood from the lower, or lower brain from the higher. We have *nervous* symptoms, the result of this overstrain of nerve-centres, and the disturbance of the equilibrium of the circulation, thereby brought about.

The point that has particularly attracted my notice, was an allusion to the condition of the urine in one of the cases. It was described as dark brown, of high specific gravity, containing a trace of sugar. I have seen such cases, and think it not unlikely that the apparent sugar reaction is really due to uric acid, which is often abundantly present in these urines of deranged digestion. If we get rid of the excess of uric acid by allowing it to precipitate spontaneously, or precipitate it by the addition of an acid, the sugar reaction with the copper tests does not take place. Other characters of the urine, particularly its dark color and scantiness, are not usual to sugar-containing urine.

DR. ESKRIDGE: The most important point in the subject is whether the condition called neurasthenia is primarily a nervous disorder, or a disturbance in other parts of the body. Those who have paid attention to this subject say that breakdown does not occur unconnected with either worry or vice. I have never seen a case from mental overwork alone.

It appears to me that nervous prostration, so-called, is a depressed condition of the whole system, the trouble manifesting itself as a general nervous condition secondarily, after organs other than the brain have been primarily affected. The therapeutics also favor this view, because the cases are benefited, not by agents addressed to the nervous system alone, but by hygienic and tonic measures.

DR. BARTHOLOW, in closing the discussion, said: The great question is, Is neurasthenia functional, or does it arise from organic change in the nervous system? I maintain that it is largely reflex and frequently from gastric disturbance. Neurasthenia in women is associated with an anæmic condition and ovarian and uterine disorders. They are pale and weak, and if they are subjected to any moral or mental trouble give way, but if they are well nourished, sustain any kind of shocks without suffering in health.

Worry has been mentioned as a cause of nervous exhaustion; now, worry hurts a man just in proportion to his condition. If he is in good health, or phlegmatic in temperament, the worry may be well borne; but if he is out of health, worry will have a powerful effect on the nervous system. I do not deny that various causes may produce brain disease, but I deny that the so-called neurasthenia is due to an organic lesion of the nervous system. I maintain that it is part of a morbid complexus; a reflex condition, in large part, of maladies situated in the stomach, the liver, the uterus, or other organs.

DR. WM. S. LITTLE then read a paper on

EYE SYMPTOMS AND CONDITIONS IN BRIGHT'S DISEASE.

Among nine hundred and eleven cases of Bright's disease reported by different observers, changes in the retina have been observed to be associated with the kidney affection in twenty per cent. The recognition of Bright's disease from lesions in the eye, in a case already diagnosed from symptoms in other organs, is not of so much importance for diagnosis as it is a help in forming a prognosis; nor does the condition existing in the eye demand the therapeutics of special medicine.

Retinitis, generally symmetrical, if not always so, appears in all forms of kidney disease, while it is principally associated with the chronic disease of the cirrhotic kidney. Even though symmetrical, its presence is not always known to the patient; especially is this so, as long as the region of the macula lutea in the retina is not affected, so as to produce a central scotoma; lesions near the nerve and peripheral parts of the retina are not so productive of recognizable scotoma in the field of vision. These cases do not have the restricted visual field and rarely the loss of color-sense that belong to the optic nerve and brain troubles or contracted field of glaucoma. The symptoms may correspond to those of retinitis from any other cause: flashes of light, color sensations, dread of light, impaired vision, to total blindness.

While the lesions occur generally near the optic nerve and to the temporal side, the nerve itself is not implicated to the degree that might be expected from the picture it presents; the separate spots in the retina finally coalesce, approaching the disk, and involving it; in other cases they surround the region of the fovea centralis, and are much smaller. They may occur anywhere in the retina, varying in size; the shape is somewhat quadrilateral, but may vary as they progress; they present a white appearance. The tissue near the disk and the disk itself appear striated; spots of hemorrhage are found from rupture of retinal or choroidal vessels; opacities in the vitreous are seen. The state of pigmentation is the latest. In chronic cases the color of the fundus is peculiarly yellow, and the character of the picture is at times very much like the neuro-retinitis of brain disease or pernicious anæmia.

The changes result from the hyperæmia and infiltration of the tissue, fatty degeneration and atrophy producing changes in the bloodvessels with hemorrhage; a fatty deposit in the retinal tissue; the fibres of the retina become sclerosed, and pigmentation follows.

The optic nerve is not seriously involved, though gray degeneration may exist, and numerous amyloid bodies may be seen with the microscope. The retina does not always present all the stages described; the kidney disease being amenable to treatment, the retina may not undergo any further change; where it is chronic, a like progression ensues in the retina. Marked lesions at times disappear, leaving only a slight trace. The hemorrhagic state is more severe, the sight not only being lost, but the patient's life endangered.

The prognosis, so far as vision is concerned, is serious, when the region of the yellow spot is encroached upon, and yet fair vision may remain after subsidence of the disease.

Can a prognosis as to the duration of the disease or to its fatality be derived from the eye symptoms? Only in the chronic stages of the disease, when retinal hemorrhages are extensive and repeated, the heart being diseased. Traube considered the heart the immediate cause of these retinal hemorrhages; but they exist in cases without heart trouble, and in other diseases of the system, and in intraocular conditions. Brain symptoms soon follow in these severe types of retinitis, in chronic kidney disease a general hemorrhagic condition being developed, or uræmia may ensue. In the acute forms of Bright's disease no prognosis of any value can be formed from the eye symptoms, though severe.

As to treatment of the eye in this disease; what renders the disease of the kidney controllable, is only of advantage to the retina; leeching may be useful if the

patient is not too anæmic. For the vitreous opacities, in cases where the disease is under control and the acute condition of the eye abated, electricity is of considerable value, much more so than any plan of medication.

DR. ALBERT G. HEYL desired to direct attention to the relation which exists between the intraocular phenomena observed in Bright's disease and the anatomical arrangement of the intraocular arteries. The latter are divisible into certain areas; thus we have one area composed of the arterial circle of Zinn, which supplies the optic papilla; another formed by the arteria centralis retinæ, which supplies the retina; another composed of short posterior ciliary arteries, which supply the posterior half of the choroid; yet another composed of the long ciliary arteries which supply the iris and the anterior half of the choroid; the short anterior ciliary arteries also take part in the formation of this area. Now, it is established that abnormal changes in connection with Bright's disease may exist primarily in each of these areas, with perhaps one exception, to be mentioned directly. Thus the papillary area may be affected, and a papillitis will be found on examination, the choroid and retina and iris being unaffected. Again, the posterior choroidal area may be affected, and there will be found the phenomenon of subretinal œdema, and also in the choroid the white accumulations so well known in connection with Bright's disease. Both of these forms are considered to be rare; perhaps they would be observed oftener were we more alert. A case reported by him (THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, October, 1874) of retinal separation occurring in one eye, while simultaneously the other was affected with temporary amblyopia, probably belonged among the affections of the posterior choroidal area. Further, the retinal area may be affected, and the peculiar retinal appearances so well known are found. So far as he is aware, no separate affection of the irido-choroidal area had been described; there seems to be no reason why it should not occur. Of course there are many cases in which the areal lesions exist together, but they are to be looked upon as the result of one common cause, not as the result of a morbid process starting in one area and gradually implicating the others.

In referring to the snow-like patches of the fundus, commonly looked upon as the characteristic intraocular appearance of Bright's disease, he thought that to a certain extent they are to be looked upon as the remnants of intraocular hemorrhage. While hemorrhagic clots formed of normal blood are absorbed without any whitish residuum being left, the case is different where the blood, as it circulates in the vessels, is in a morbid state. Thus, in a case of pernicious anæmia, he has observed a number of round red hemorrhagic spots with white centres. On examination ten days later the red coloring-matter of the hemorrhages had largely disappeared, leaving as a residuum white masses. Some of these were speckled with red points, arranged in spindle form like the hemorrhages of the retinal nerve-fibre layer. They were, however, simply the unabsorbed remnants of the round hemorrhagic spots seen ten days before. So in morbus Brightii, the blood is in such a morbid condition that hemorrhagic clots rapidly lose their red coloring by absorption, leaving behind a white residuum which may partially, at least, explain the white plaques seen with the ophthalmoscope.

DR. JAMES TYSON then presented a note on some

RECENTLY SUGGESTED DELICATE TESTS FOR ALBUMEN.

He said that recently several delicate tests for albumen have been suggested by different observers. Among them are: 1. A saturated solution of picric acid; 2. Saturated solution of ferrocyanide of potassium after free acidulation by citric acid; 3. Standard solution of potassio-mercuric iodide,[1] after acidifying the urine by citric acid; 4. Equal parts of a saturated solution of sodium tungstate (1 in 4), saturated solution of citric acid (10 in 6), and of water; 5. Acidified solution of potassio-mercuric iodocyanide. To complete our list of available tests we may add: 6. The ordinary heat and acid test; 7. The nitric acid test, by Heller's overlaying method; and, 8. The acidulated brine, consisting of an ounce of hydrochloric acid added to a pint of water saturated with common salt, and filtered.

The whole subject of these delicate tests has been gone over by Dr. George Oliver, of London. As all of the tests which are not distinctly acid require the previous acidulation of the urine, Dr. Oliver has modified the picric acid solution by adding two drachms of citric acid to one ounce of the solution. Leaving out the potassio-mercuric iodocyanide as a solution troublesome of preparation, Dr. Oliver's results as to all the other tests just named are as follows: Adopting the method of overlaying the test solution by the urine (all of them as above prepared are specifically heavier than ordinary urines, while the pure picric acid solution is lighter), *one part of albumen* may be detected in

PARTS OF URINE.		TESTS.
20,000	by the	Iodo-mercuric, Picric acid, Tungstate.
10,000	by the	Ferrocyanide,
12,000		Acidulated brine.
6,000 to 7,000	by the	Heat, Nitric acid.

Dr. Tyson said: I have carefully repeated Dr. Oliver's testings, and have arrived at results which, while not identical, may be said to be practically the same—except, perhaps, in the case of heat and acid combined, which I find decidedly more delicate than the pure nitric acid, and more delicate than the acidulated brine solution. So, also, I do not find the sodium tungstate solution quite as delicate as the picric acid and the potassio-mercuric iodide; but they may be placed in the same category. As the result of this experience, it appears to me that the use of nitric acid may be altogether substituted by the acidulated brine, as a solution at once more delicate and, on account of its non-corrosive properties, altogether more satisfactory to manipulate.

In THE MEDICAL NEWS for October 27, 1883, Drs. Cooke and Watkins prove that the urine of persons taking six grains of quinia or cinchonidia daily will invariably give a precipitate with picric acid, nine or ten hours after the administration. Also, that solutions of sulphate of quinia and of cinchonidia containing $\frac{1}{120}$ grain gave a decided precipitate, and one containing $\frac{1}{180}$ of a grain an appreciable precipitate. With a view to testing these results, I tested my own urine on a

[1] Mercuric chloride, 2.7 grammes; potassium iodide, 6.4 grammes; distilled water, 100 cubic centimetres.

given day with picric acid, and found no response. On the following day I took twenty-two grains of sulphate of quinia in three doses, taking the last dose at 6.30 P.M. The urine passed at 8.30 P.M. gave a beautifully distinct white line, when overlaid by a pure picric acid solution. So also did the urine passed at 9 A.M. the next day; but that passed at 3 P.M did not respond. I also found that a solution of sulphate of quinia containing $\frac{1}{100}$ of a grain to the fluidounce responded similarly. I then repeated the experiments with the remaining tests, and found that the potassio-mercuric iodide gave identical results with the picric acid solution, *but that the sodium tungstate and ferrocyanide of potassium solutions did not.* So that we shall have in these two solutions, and particularly in the sodium tungstate, a test solution more delicate than heat, acid, or brine, which does not precipitate quinine in solution.

Picric acid has also been shown by Dr. George Johnson to precipitate artificially prepared peptones. And the same is true of potassio-mercuric iodide and sodium tungstate; and as peptones have been shown to be present in a considerable number of urines, they must be admitted as possible sources of error, the exact importance of which is as yet to be determined. The ferrocyanide solution does not precipitate peptones, but, in common with the others, occasionally precipitates amorphous urates. But these, behaving precisely like the amorphous urates thrown down in the Heller test by nitric acid—that is, forming a smoky cloud rather than a distinct layer, and being easily dissipated by a moderate heat—need not be a source of error. An excess of albuminous urine dissolves the precipitate formed by picric acid, but this need not be a source of error. It is said, too, that potassium salts are precipitated. But, so far as we know, no other agencies likely to be found in urine can lead to error; so that, if we remember to eliminate quinine as a source of error, the picric acid solution, acidulated with citric acid, is still an available test of great delicacy, which is further recommended by its cheapness and easy preparation; although, so far as our present knowledge goes, the sodium tungstate solution is the best, and least liable to cause error.

DR. DULLES said that the error caused by the precipitation of quinine by picric acid, may be corrected by adding nitric acid, which dissolves the quinine precipitate, but not that of albumen.

DR. LEFFMANN said that he has found the glacial phosphoric acid the most delicate and easily applied test.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 8, 1884.

THE PRESIDENT, WILLIAM J. MORTON, M.D., IN THE CHAIR.

NOTE ON THE USE OF THE MENTHOL CONE AS AN ANODYNE.

DR. E. C. WENDT showed a little contrivance, called by the Germans *Migräne Stift*, and explained the method of its application and uses. It consisted of a piece of menthol moulded into a conical shape and secured in a little wooden box, closed by a cover to prevent evaporation, soiling, and breaking. It seemed to be very little known here, although it is much used abroad, especially for sick-headache. His attention had been first directed to the anodyne properties of menthol by a short notice, published in the *Medical Record* of April 28, 1883, by Dr. Cammann. That gentleman had recommended an alcoholic solution of menthol (℥j to ℥ss alcohol) to be painted over the affected parts. Dr. Wendt had since that time often used this solution, and found it a rather reliable anodyne. Its pain-relieving action was restricted, however, to the slighter ailments, especially those of neuralgic character. Since his acquaintance with the solid menthol cone, he had frequently substituted the direct application of menthol, by means of the latter, for the solution formerly employed. He would admit that the only advantage which the solid cone or pencil had over the solution, consisted in the greater simplicity of its application, its ready portability, and the fact that its vapor was not apt to irritate the eyes of susceptible patients. He had repeatedly heard complaints in that direction from ladies, regarding the solution, which was obviated by using the cone.

In this country menthol had not yet received that amount of recognition from the profession, to which its pain-obtunding properties would seem to entitle it. In fact, little seemed to be known about it, and for this reason Dr. Wendt thought it might not be amiss to quote a descriptive notice which had appeared in the *Midland Medical Miscellany*, of October, 1883.

"Menthol or menthylic alcohol, $C_{10}H_{20}O$, is a crystalline substance, deposited from the oil of peppermint, prepared in China and Japan from *Mentha Arvensis var. Piperascens and Glabrata.*" It formed the chief ingredient of a much valued remedy for neuralgia before its nature or source was generally known. Under the name of po, ho, yo, or *Gouttes Japonaises*, it has been sold in small bottles, labelled with Chinese characters. It is a white crystalline stearoptene, melting when pure at 97° Fahrenheit, and is obtained by the Japanese from the oil of peppermint, by submitting it to freezing several times in succession until no more menthol crystallizes out. It is also said to be contained in the American and English oils of peppermint, but probably in small quantities only. It is somewhat surprising that the Japanese peppermint plant which is grown in England as a curiosity, has not been cultivated in that country as a source of the drug, the supply of menthol being uncertain, the demand great, and the price in consequence occasionally very high. Menthol is said to be sometimes adulterated with crystals of Epsom-salts, to which it bears a great resemblance. These being insoluble in alcohol or chloroform, in which fluid menthol is freely soluble, can easily be detected. Samples of fine crystals sometimes contain some essential oil adhering to them, a fact which must be taken into consideration when the menthol is made into cones or pencils. Menthol is but slightly soluble in water, although imparting a strong odor and taste to that liquid, and is insoluble in aqueous alkalies. It is soluble in fixed and volatile oils and in ether.

Although Dr. Wendt's experience with menthol had not been a very extended one, it had nevertheless been sufficient to convince him of the utility of the drug, in a rather large class of cases. Thus, as already stated, he had found it a very pleasant and reliable anodyne in all the lesser neuralgias, and especially in those so frequently occurring about the face. But it was also ser-

viceable in many painful affections due to inflammatory processes. For example, in mumps, in the cervical adenitis so often accompanying sore throat, and in numerous other affections where pain was a prominent symptom, menthol might be used to advantage. With regard to its topical action, it was similar to that of aconite, over which it had the advantage of not being poisonous.

Dr. Wendt remembered one rather striking case of quite severe supraorbital neuralgia, which refused to yield to the oleate of aconitia, but was much benefited by the menthol. But, on the whole, in violent attacks he had found it almost useless. In typical migraine, for instance, where the pain was at all severe, and in all deep-seated aches of more than very moderate intensity, it had no appreciable effect, except, perhaps, the indirect psychical action of distracting the sufferer's attention.

In the discussion which followed these remarks, DR. ROBERTS asked Dr. Wendt if he had tried the prolonged application of menthol.

DR. WENDT said that he had in some cases of hemicrania, though without decided benefit. Nevertheless, the patients experienced a pleasant sensation of coolness of the surface followed by a feeling of agreeable warmth.

DR. MORTON desired to ask Dr. Wendt, in what sense he used the word anodyne. Dr. Wendt said in the usual one, of affording relief from pain by blunting sensibility.

DR. MORTON thought that menthol probably acted more after the manner of counter-irritants, by insuring relief in a reflex rather than directly local way. Mustard was a typical peripheral nerve-irritant, and it seemed to him that the action of menthol could be best explained on the same principle, of procuring peripheral nerve-impressions in a reflex way.

Dr. Morton stated that his attention had been first called to the menthol cone by Dr. Wendt. He chanced to be at the latter's office one day when suffering from a headache. A few strokes of the menthol gave him at once a sense of relief. He felt the effects of the peppermint to be as gratefully cooling as the application of, say, cold metal. In brachial neuralgia, as well as in sciatica, he had been pleased with the good effects of menthol. He thought the drug was deserving of further trials.

CORRESPONDENCE.

THE PRESENT STATE OF MEDICINE IN JAPAN.

To the Editor of THE MEDICAL NEWS.

SIR: As the word Japan seems to open visions of El Dorado to all non-resident aspirants to fortune, and lest the heading of my letter should incite some of my brethren to its perusal in hope that it may prove in some sort a directory to the, presumedly, overflowing wealth of the Orient, let me begin by a word as to the status and prospects of European and American physicians in this portion of the Far East. As to present status, those medical men now here, save of the small and rapidly decreasing number in government employment, are doing, and must do, more work for less remuneration than in even our smaller cities at home, while the expense of living in decent comfort is far greater in Japan than in the United States.

This country is now passing through a severe financial crisis; business of every kind is at a standstill, and as the foreign practitioner must depend almost exclusively upon the foreign residents for his support, the depression of trade affects him severely. It is but rarely that the services of a foreign doctor are called for by the natives, first, because the majority of these much prefer their own physicians; second, because they are rarely able to pay for his services—in fact, cannot understand that a physician's time or advice has any money value, the old custom—still almost universally in force—being to pay the medical attendant for medicines furnished, for which alone the physician has a legal claim to remuneration, and to pay, or not to pay, in addition, an honorarium generally ridiculously small, and entirely a voluntary matter; third, because in the larger cities of the Empire there are foreign medical officers attached to the Government hospitals, whose advice can be had by the richest at an expenditure amounting to little more than the wholesale cost of the medicines prescribed. The number of foreign doctors thus employed is now small and diminishing, their places, at the expiration of their contracts, being filled by natives educated abroad, or at the Imperial Medical School mentioned hereafter. Our services—I speak as one of the resident foreign physicians—are even less in demand by the natives than formerly, for Japan has, perhaps, made more real and solid progress in medical science than in any other branch of western learning, and has now a considerable number of fairly good men—either educated in foreign countries, where some have won honors, or under foreign instructors in the Government hospitals and medical schools at home. In addition to these better men, who, of course, are found only in the Imperial service or in the larger cities, there is to be found in almost every town of the Empire at least one native physician practising, so far as his education will permit, according to the modern system.

The Government offers every encouragement for the advancement of the native practitioners in modern science. The innumerable appointments in its gift are bestowed only on men of the new school, while, as regards those practising privately, a system of examination and graduated license has been put in force throughout the Empire, which would afford no bad model for adoption in some of the United States.

Japan has now a considerable literature of modern medicine, which is rapidly increasing, and there are also something like a dozen medical periodicals, well supported. It is true that the execution of the translations, which compose the bulk of the literature in question, leaves much to be desired, yet the essentials of the original are generally preserved, and gross errors infrequent.

Ten years ago, the number of books on modern medicine in the Japanese language could have been counted on the fingers of one hand, while the writer at that time established, under Government auspices, the first medical journal of the country. A few months ago, a shipment of some four hundred volumes of medical text-books was sent to the library of the Surgeon-General, U. S. A., at Washington, and nearly as many more will shortly follow. Many of these are really beautiful reproduc-

tions of expensive illustrated works from the presses of Europe or America, though original treatises of almost equal mechanical execution are not wanting. It follows that, should any of your readers wish to investigate for himself the state of medical literature in Japan, he will find material within reach, the library mentioned containing, in addition to the above-mentioned books, full sets of the leading medical journals of this country.

The exquisite workmen of Japan have, of course, undertaken the manufacture of surgical instruments and apparatus — almost all known surgical appliances, of native manufacture, being found in the shops of the dealers in medical supplies. In appearance and finish, the instruments of domestic manufacture are indistinguishable from those imported, and, with the important exception of those whose value depends upon the quality and temper of the steel employed, are equally useful. It is difficult to understand the failure of the native artisan in the construction of small articles of steel, for the Japanese metal is second to none in the world, as will be readily granted by anyone who has seen the tests endured by a Japanese sword of good quality. When this difficulty in the management of small articles of steel shall have been overcome, as no doubt it speedily will be, the Japanese surgeon will be able to furnish himself more cheaply than in any other country.

It will be seen, then, that so far as material goes, the means are not wanting for the theoretical education or the equipment of every native student, while the many and often admirable hospitals maintained by the Imperial Government, or by subscription, afford good opportunities for clinical study.

Facilities for anatomical work are, however, sadly lacking. Though Japan has an anatomy law, which many of our benighted States would do well to copy, its operation is so hampered by the prejudice and mistaken benevolence of the people, that even in the great city of Tokio (Yedo) the Imperial School of Medicine is unable fully to supply its students with anatomical material, while in the provincial hospitals and schools opportunities for dissection are rare indeed. Realizing the value of anatomical study, and the difficulties in the way of its pursuit, efforts have been made to compensate for the want of actual dissection by the publication of elaborate atlases and anatomical wall-plates, and even by the reproduction in fac-simile of Auzoux's great manikins at a price of about one-third the original. The lack of facilities for the study of practical anatomy is the more, perhaps, to be regretted from the fact that the Japanese excel in many of the qualities which go to make a successful operative surgeon. Steady nerve, marvellous dexterity, mechanical tact, and a power of mentally reconstructing form that is absolutely astonishing, are qualifications to which, if a knowledge of anatomy were added, the product should be a surgeon above the average.

À propos of this power of recalling form, which is almost universal among the better class of Japanese, I am inclined to attribute it to the personal and hereditary influence of training in the use of the Chinese character, a knowledge of several thousands of which complicated and arbitrary forms is necessary to every Japanese who would either read or write anything esteemed of value. The æsthetic sense of the race may also have influence in this direction.

I have spoken of the Imperial School of Medicine at Tokio (Yedo), and of the larger hospitals throughout the country, as affording opportunities for instruction under foreign teachers. The former is under management exclusively German, and, in fact, of late years, German physicians have had almost entire control of the medical education of the country. With many others of long experience among the Japanese, I believe this to be a sad mistake, the more so as the curriculum of the Imperial School is modelled almost exactly upon that of the German universities. Quick, ready, and intelligent as the Japanese undoubtedly are, their mental calibre is, in many respects, that of precocious children, and their science is, and for a considerable period must remain, imitative and routine. With the concrete, the native mind is familiar and expert; with the abstract, it can do little. What Japan needs, at this time, is a considerable body of men sufficiently educated to deal with the ordinary diseases of the country, and she needs them urgently. What the Imperial School is endeavoring to do under the disadvantages of the use of a foreign language, useless for any other purpose of study or business, for which English is universally preferred, enforcing new methods of thought, and having an eminently practical race to work upon, is to turn out men fitted for original investigation of the deepest mysteries of science and versed in all the theories of modern medicine, proved or purely hypothetical. What this school really does, is, yearly, to graduate the few who are found physically and mentally competent to stand the strain, having all the faults of the German school of medicine in aggravated degree, therapeutic nihilism their creed, and holding the welfare of the patient even more entirely subordinate in interest to the natural history of the case, than do their teachers.

That Germans now have the preference in Japan, as teachers, in almost all branches of science and literature, is probably due to the fact that the more conservative members of the Government feel that the country has progressed rather too rapidly toward free thought and free institutions, and believe the political system of Germany to be more in accord with that desirable for Japan, than those of England and America. The students themselves, however, much prefer the English language and English and American books, even as regards medicine, and it is chiefly from these sources that the present literature is derived.

The old school of medicine in Japan was nearly identical with that of China, a melange of superstition and an absurd and utterly artificial system of anatomy and physiology, with the results of ages of empirical practice —the latter having led to a more or less correct appreciation of the use and value of many medicines used by ourselves, *e. g.*, mercury, antimony, and aconite. In addition to a vast number of plants and minerals, animal substances form an important element of the old pharmacopœia. Whole cargoes of dried fœtal deer are yearly shipped from the island of Yezo to southern Japan and China; while dried lizards, tigers' claws and teeth, bears' galls, monkeys' skulls, and other even more repulsive substances, are largely used. In fact, the Chinese practitioner of to-day is working with much the same armament as did our predecessors in the not very long past time when treacle of mummy was a panacea. But, absurd and disgusting as the materia medica of the

old school of medicine in Japan and China may at first glance appear, it is probable that in their immense, and to us little-known, field of natural resources the empiricism of a shrewd people has discovered some therapeutic agents of value, and such as would repay a thorough investigation of their pharmacopœia by some medical Sinalogue. I will return to this subject further on.

Although trained in the same school and holding allegiance to the same ancient authorities, the essential difference between the stolid conservatism of the Chinese and the active and progressive disposition of their insular neighbors, was shown even before the opening of Japan to foreigners generally, by the attainment of a partial emancipation from the thraldom of the old school through the voluntary efforts of native practitioners, and this, too, at a time when even to read a foreign book without the special permission of the Government was a capital offence. A native doctor, having accidentally seen a volume of anatomical plates at the Dutch settlement of Nagasaki, returned to his distant home disquieted and anxious, realizing that if the drawings he had examined were correct, his whole system of science, based as it was on different premises, must fall to the ground. Unable to prosecute research upon the human cadaver, he carefully dissected all the quadrupeds he could obtain, and finding, throughout, close similarity to each other, and to the pictures he had seen, he at last, after great labor and no little danger, obtained permission to dissect a criminal. This dissection settled the question for himself and friends, for the science of the western foreigner was vindicated. From this began a movement, resulting in permission being given that a limited number of natives might study under the Dutch surgeons at Nagasaki, and in the translation of a few medical treatises of an elementary character.

Another instance of progress is even more remarkable, as it was entirely independent of assistance from without. A native physician, belonging to a family with whom the practice of the obstetric art was hereditary, for male accoucheurs have long existed in Japan, though in small number, after many misfortunes in the line of his practice, and a long time devoted to study and investigation, elaborated a fairly complete system of midwifery, and published an illustrated treatise on the subject. Kagawa Shigen found the obstetric art of Japan in a condition little, if any, better than among the American Indians of to-day; he left it almost upon a par with that of Europe before the invention of the forceps. He invented a number of convenient and practical instruments, which, though in some respects resembling others of European origin, differ sufficiently from these to prove independent evolution, while his book, which affords intrinsic evidence of originality, contains a series of really valuable precepts and clinical observations. Unfortunately, like the Chamberlens, Kagawa attempted to keep his improvements secret within the limits of his own family, and, unlike the Chamberlens, succeeded, until recently, in so doing. A descendant of the reformer is to-day practising in the capital, and exhibits so little of the ancestral spirit as to ignore all science save as contained between the covers of his inherited manual.

The aged Solomon's grumbling remark, that there is nothing new under the sun, seems to derive much confirmation from the Orient, and it need hardly surprise one greatly to learn that any of our supposed recent discoveries were anticipated ages ago in the Far East. Am I wrong in believing that the extract of malt is esteemed by many as one of the most recent triumphs of restorative medicine? The Japanese and, to some extent, their Celestial neighbors have used this article, or something closely related thereto, for centuries. The experience of my foreign colleagues and myself in the medicinal use of the native preparation has been so favorable that I cannot refrain from a few remarks upon it, even though quite aware that this long and gossiping letter should ere this have been brought to a close.

The article in question is known in Japan as "ame" or, in its better form, as "midzu ame," and as it is the latter which is most convenient and valuable for medicinal use, it is of this variety that I shall chiefly speak. Midzu ame, of the best quality, is a clear, transparent, faintly brown, or amber-colored syrup, or may have the consistence of candy, according to the amount of water contained. If properly prepared, it ferments only with difficulty, and long keeping changes it only by inspissation. The flavor is pleasant; so much so that some of our foreign residents prefer it, for table use, to the best imported syrups, while, when used medicinally, it rarely becomes distasteful, even after prolonged administration.

To describe in detail the manufacture of midzu ame would occupy too much space at present. Suffice it to say that it depends upon the now generally known fact that starch, in the presence of malt in solution, is converted into a saccharine body (maltose). The malt used is, as elsewhere, derived from barley, germination having been allowed to proceed to a greater extent than is usual with us; the starch is that of rice or millet, preferably the former, of which a peculiarly glutinous variety is chosen.

The consumption of ame in its different forms is enormous in Japan. The cheapness of the article, as compared with sugar, renders it the basis of a large proportion of the confectionery used. I have spoken of its use by the natives medicinally; it is, however, only as a digestible and strengthening food for the aged and for hand-fed or weakly infants, that it has, until very recently, been prescribed, and from this point of view alone midzu ame will be found well worthy of trial elsewhere. So far as children are concerned, I know nothing more useful for the feeble or bottle-fed than the article in question. During the past five years, the writer having been first to call attention to the subject, midzu ame has been largely used by both foreign and native practitioners in cases of dyspepsia and malassimilation, of almost every variety, with such success that the consumption of the better qualities has considerably increased, while several manufacturers are now devoting themselves to the production of special grades for exclusively medical use.

Midzu ame ranks as a food close to cod-liver oil, for which it will often be found to be an efficient substitute. In many cases of phthisis it has proved so useful that I shall not be surprised should the lapse of time show that ame is quite as valuable in this disease as is the oil. It is, however, of its use in dyspepsia that I would specially speak. An experience of several hundreds of cases, both native and European, and in conditions varying from mere sluggishness of digestion to almost total and fatal inanition, has demonstrated that ame is

far more than an easily assimilated food. This it certainly is; but it has, in my opinion, a power to assist in the conversion of other food beyond that of any agent heretofore employed, and is to be relied upon to exert the action which we hope for from pepsin, artificial gastric juice and the like, but in which we are so often disappointed. It is probably this power which, in cases characterized by active fermentation, acetic or butyric, enables the ame, saccharine body though it be, to act as an anti-ferment, for it is in this class of cases that the benefit derived from its use is most speedily manifested.

Granting the foregoing statements to be correct, it will be seen that we have in the article under consideration a nourishing, agreeable, and easily digested food, which can often be taken, and duly appropriated, after cream, raw beef, acid emulsions, and the like, have failed, and which will frequently secure the digestion of more or less other food, almost from first administration. I would not be understood as asserting that this contribution from the Far East is either infallible or specific, but that it has often saved life and, in an immense number of cases, restored health, even after the failure of approved treatment, I am certain, as well as that the experience of most of my colleagues has been equally favorable.

It is to be hoped that an opportunity may soon be given for a thorough and unprejudiced trial of ame in the United States, and that, in order that such may be secured to it, whoever undertakes its introduction will put it in the hands of the profession only, in proper manner, and without the clap-trap and advertising falsehood which repel every honest physician from what may, perhaps, be a really valuable and much needed article.

Medical Director of Imperial Hospital of Kanagawa Ken,
Surgeon in Charge of the Foreign General Hospital of Yokohama.
YOKOHAMA, JAPAN, December 20, 1883.

NEWS ITEMS.

PUBLIC HEALTH.—Mr. Green, of North Carolina, introduced in the House of Representatives, last week, the following preambles and resolutions, which were referred to the Committee on Public Health:

Whereas, It is popularly charged, and generally believed, that divers and various articles of food, drink, and medicine are adulterated by admixture with baser and usually deleterious substances; and,

Whereas, Such adulterated compounds are injurious to public health, and calculated to shorten human life, therefore, be it

Resolved, That the Committee on Public Health be authorized and directed to inquire into the truth of said alleged abuse, and to report to this House the result of their investigation at as early a day as practicable; and, if it shall be shown that such practices exist, then to suggest or recommend in their report what further legislation, if any, is necessary to correct the wrong; and, that they may more effectually do their work, be it further

Resolved, That said Committee be, and they are hereby, empowered to send for persons and papers, and to employ such medical and chemical experts as they may deem necessary to carry out the end, aim, and object in view.

THE NEW YORK STATE MEDICAL SOCIETY AND THE CODE CONTROVERSY.—The annual meeting of the New York State Medical Society occurs at Albany this year on Tuesday, February 5th. At this meeting three distinct propositions in regard to the ethical question, laid over from the last meeting, will come up for action. The first of these in order is the no-Code proposition, or the declaration and resolution to abolish the present New Code. The second in order is a proposition to repeal the action taken on the Code at the meeting of 1882, leaving the Old Code to stand as it was prior to that action. This comes up as an amendment to the by-laws. The third is a proposition to substitute the National Code for the New Code. Then, when representation in the American Medical Association is regained, that the delegates of this Society be instructed to advocate such modifications in the National Code as may make it more liberal, or, if advisable, to urge its entire abolition.

All these propositions are amendments of the by-laws, and therefore require for adoption the "consent of two-thirds of the members present at an annual meeting."

They will probably come up in the order in which they were recorded, and that is as above given.

The first, or no-Code proposition, cannot possibly be carried without the New Code advocates, and these latter must have a two-thirds majority present in order to do it. That, too, will be impossible, unless the Old Code advocates absent themselves from the meeting in greater numbers than ever before since the adoption of the New Code. No Code is the only rational and logical position of this movement, and it is therefore doubtless the ultimate aim of the movement, and may be brought forward every year until it is carried, but its success this year is improbable.

If the second proposition be carried, the third will fail or be modified. But if the second fails of a two-thirds vote, the third will almost necessarily fail also, although it has a somewhat different aim. Neither will be allowed to succeed if the new movement can prevent it.

The time for any further discussion of any such proposition seems now to be past, and they will therefore probably be put upon their passage without the disagreeable wrangling and parliamentary tactics which have disgusted and disheartened so many conservative members, and probably kept them away from the late meetings. At least, there is no use, nor any common sense, in any renewal of strife. The Society is now hopelessly split, and that upon a principle of honor, or at least upon a basis which is assumed to be such by both sides of the split, because the revolutionists consider themselves as much bound in honor to destroy the old ethical basis of the Society's organization as the conservative element does to protect and defend it. And when a principle is involved, to yield is to submit. The vote, therefore, is to be for the final possession of the Society, and whichever party is defeated, must withdraw and form new organizations if they desire to have them. Hence, as a matter of professional principle and honor, it seems to be the professional duty, as it should be the pride, of every delegate and permanent member

of the Society, to go to this meeting and record his name on one side or the other of this vital issue. Doubtless, the Society will go on and flourish under whichever party gets the ascendancy, but so radical is the difference that it can never again flourish under both. The objects, means, and methods being radically different, it would only paralyze its usefulness to attempt to blend them, and therefore this coming vote is to decide into which of two very different channels the Society will in future direct its usefulness. In either channel it may or may not do as much good as before, and if not, the new organizations that may grow out of the division may more than counterbalance the deficiency. As both sides cannot now occupy the same ground, the question simply is, which shall hold it? and in this decision every man entitled to a vote on either side should see to it that his name is fairly recorded upon the side of his choice, after the full deliberation of two years. Whether his side succeeds or not is by no means the most important consideration, important though it be. The main point is to have his individual position clearly and unmistakably defined. The vote should, and doubtless will be, by ayes and noes, since both sides should be equally determined to have a full and clear record.—*Ephemeris of Materia Medica*, January, 1884.

THE NEW CODE IN CONGRESS.—Senator Hale introduced in the Senate, on Tuesday last, a bill "to secure to the medical profession equal rights in the service of the United States," which provides that all appointments to medical service under the Government shall be made from graduates of legally chartered medical institutions, without discriminating in favor of or against any school or theory of medical practice.

NEW YORK COUNTY MEDICAL ASSOCIATION.—The officers of this new Society are:

President.—Wm. Detmold, M.D.
Vice-President.—C. A. Leale, M.D.
Recording Secretary.—E. A. Judson, M.D.
Corresponding Secretary.—W. V. White, M.D.
Treasurer.—A. S. Church, M.D.

At the first meeting, held last week, at which Dr. Flint's paper was read, there were about three hundred physicians present.

LIBERAL BEQUEST OF DR. ELLIS TO HARVARD UNIVERSITY.—By the will of the late Dr. Calvin Ellis, his estate is left in trust for the benefit of his sister, and upon her decease fifty thousand dollars goes to Harvard College, the net income of which, after deducting five per cent. for the purpose of increasing the fund, is to be applied to the payment of the tuition and other expenses of certain descendants of Davis Ellis, and others who may be members of the College. The residue of the trust property, if any, is also to be paid to the President and Fellows of Harvard College, the income, after the same deduction of five per cent., to be applied to the payment of a salary of a professor of pathological anatomy, under certain regulations as to the amount of such salary.

ANNALS OF ANATOMY AND SURGERY.—It is announced that on account of the departure of the senior editor, DR. PILCHER, for Europe, and the expected departure of his colleague, DR. FOWLER, the publication of the *Annals of Anatomy and Surgery* is necessarily suspended during their absence. If circumstances shall seem to warrant the resumption of the journal with the beginning of another year, due notice will be given.

THE OHIO STATE SANITARY ASSOCIATION will hold its first meeting February 14 and 15, 1884, in the city of Columbus.

INTERNATIONAL MEDICAL CONGRESS.—The following list of subjects is proposed for communications and discussions in the Section of Dermatology and Syphilis:

1. On the Syphilitic Origin of Tabes.
2. Treatment of Syphilis with Mercurial Injections.
3. Excision of the Initial Induration as Abortive Treatment.
4. The Etiology of Leprosy.
5. On a New System in Skin Pathology.
6. The Etiology of Lupus Vulgaris.
7. The Pathogeny of Gonorrhœal Rheumatism.
8. The Term of Infectiousness of Gonorrhœa.
9. The Significance of Micro-organisms in Skin Diseases, formerly considered as Non-parasitic.—*Journal of Cutaneous and Venereal Diseases*, January, 1884.

DR. CHARLES T. PALMER, of Pottsville, has been appointed consulting oculist at the Miners' Hospital.

THE ANNUAL ELECTIONS AT THE PARIS SOCIETIES.—M. Marc Sée has been elected President of the *Société de Chirurgie*, for 1884.

M. Delpeche, President of the *Société de Thérapeutique*.

M. Bucquoy, President of the *Société Médicale des Hôpitaux*.

M. Laborde, President of the *Société de Biologie*.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending January 12, 1884, indicate that pneumonia has greatly increased; that measles, bronchitis, tonsillitis, and consumption have increased; and that rheumatism and whooping-cough have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending January 12, and since, at twelve places, scarlet fever at sixteen places, and measles at ten places.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 14 TO JANUARY 21, 1884.

BREWSTER, W. B., *First Lieutenant and Assistant Surgeon.*—Resignation accepted by the President to take effect February 7, 1884.—*S. O. 10, A. G.O.*, January 12, 1884.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE TREATMENT OF SYPHILIS.[1]

A Clinical Lecture.

BY PROF. DUJARDIN-BEAUMETZ.

(Concluded from page 92.)

GENTLEMEN: Mercury is not the only metallic substance which has been prescribed for syphilis. Chrestien and Legrand have proposed preparations of gold, Serres of silver, Hoefer of platinum, and even of copper. All these preparations have been successively abandoned, but the treatment which has had the most repute is the vegetal treatment. The anti-mercurialists, struck by the ravages which mercury occasions, had essayed to substitute for it sudorifics, and from the sixteenth century, as a result of the influence of Delgado and Ulrich Von Hutten, guaiacum was considered as one of the most powerful anti-syphilitic medicines known. The success which was then obtained by the sudorific woods depended more on the severe regimen to which the patients were subjected than to any remedial qualities in the drugs.

Since then many attempts have been made to return to the vegetal treatment, and numerous have been the compounds of indigenous or foreign herbs in decoctions and alcoholic tinctures which have been prescribed, but these anti-venereal specifics are utterly unreliable. In Italy, Ubicini Galassi and others have experimented with the root of a member of the *Cucurbitaceæ*, viz., tayuya. I have not heard of any good results from the medicinal use of this plant, and Sigmund and Geher have shown it to be completely inert. Pilocarpine, that powerful sudorific, would naturally have been employed in syphilis, and if the sialagogue and sudorific action of a medicament can have any favorable influence in the treatment of venereal disease, this alkaloid, and jaborandi, which contains it, ought to be of efficacy. Notwithstanding the results of Lewin, which have not been confirmed by other experimenters, jaborandi does not seem to have any curative virtues in syphilis.

Of this vegetal treatment, nothing remains for consideration but the ptisans and syrups called depurative, almost all of which have sarsaparilla for their basis. If the vegetal treatment is absolutely without effect, it is not so with the treatment by the iodides, and particularly iodide of potassium. Since Wallace, of Dublin, in 1832, introduced iodide of potassium in the treatment of syphilis, this medicine has always been employed in this affection, and if there is still some dispute concerning the relative value of the mercurial treatment and the iodide treatment, everybody seems agreed in acknowledging the efficacy of the latter in syphilis. It has been proposed to substitute bromide of potassium for the iodide, and I told you in a former lecture that it was these first attempts in this direction which brought the bromide before the profession. During the last few years, Garet, taking up anew the former tentatives of Richardson, Magendie, and Gambrini, has counselled the use of iodide of ammonium, but thus far iodide of potassium remains almost the sole haloid preparation used. It is given in solution, either in water or in syrup of orange-peel.

I have spoken to you many times in the course of these lectures of iodide of potassium, and shall not then return to the use of this medicine and its therapeutic and physiological effects. I shall only add, that in syphilis iodide of potassium may be given in pretty large doses, and we have seen practitioners like Puche administer from twenty to thirty grammes a day. I do not advise you to follow this example, and I believe that generally you should rest satisfied with a dose of from two to five grammes (from thirty to seventy-five grains), and that it is only exceptionally that you should administer as much as ten grammes a day, for in very large doses peculiar toxic phenomena are likely to ensue, described under the name of *iodism*.

Whenever you give iodide of potassium in massive doses, do not forget that you must prescribe at the same time the milk diet. Milk, in favoring the elimination by the urine of the iodine, and in preventing the irritant action of this salt on the digestive tube, antagonizes the baneful effects of this medication. The solution which I advise you to use is the following:

℞.—Iodide of potassium, . . 225 grs.
Water, ... 8½ fl. ozs.—M.

Each tablespoonful of this solution contains about one gramme (fifteen grains) of iodide of potassium.

You should commence with small doses, and when the iodic coryza appears, discontinue for several days the use of the medicine, to resume it in larger doses. The economy in fact habituates itself to the iodide, and persons who, at the commencement of treatment, suffer from irritations of the mucous membranes as a result of small doses, a little later may bear without inconvenience much larger doses of this medicine.

By the side of these iodine preparations, certain authorities have counselled arsenic and sulphur. The first of these has been associated with mercury in a compound which enjoys a certain popularity, and which is known under the name of Donovan's solution. Ricord has also combined iodide of potassium with arseniate of soda. As for sulphur, it has, according to Martineau, a considerable place in the treatment of syphilis. It is a sort of touchstone, which enables us (by the exanthems which it promotes) to determine if the specific symptoms have entirely disappeared,

Such is the therapeutic arsenal from which you may obtain arms to combat this disease. But I have accomplished only a part of my task in pointing out the

[1] Translated from advance sheets by E. P. Hurd, M.D., of Newburyport, Massachusetts.

armor. You must know how to use it. We shall now study in their order the treatment of the disease in general, and the treatment of the disease in particular, *i. e.*, in the patient.

We are chiefly indebted to Prof. Fournier for formulating in a masterly manner the general treatment of syphilis under the name of *method of successive treatments*. Fournier's system is based on stages of treatment and periods of repose, which latter, called by him *periods of disaccustoming*,[1] enable the economy to obtain release from habits imposed on it by the mercurial treatment, and derive the utmost possible benefit from the medication during its entire duration. So the first year he prescribes for two months the mercurial treatment, to be resumed after two months of repose; and this practice is continued with similar alternations for two years in such a manner that during the twenty-four months the patient will not have been taking mercury but ten months. At the end of the second year he administers, concurrently with mercury, iodide of potassium, and this latter medicine exclusively during the third and fourth years.

Martineau has somewhat modified the formula of Fournier, and, while following out his system of successive treatments, he gives sulphur preparations during the periods of repose. Moreover, these periods, which Fournier has traced with great care, must vary according to the patients, and no absolute rule can be laid down. I am therefore of the opinion of Mauriac, who advises that the treatment should be modified according to the march of the syphilitic manifestations.

Does this method of successive treatments rigorously followed *ensure* the cure of the patient? Unfortunately, no. If, in the great majority of cases, all specific manifestations are made to disappear by a well-ordered treatment, religiously followed, nevertheless one can never be sure that the patient is rid forever of syphilis, and you will often see arise in patients who have been treated with the greatest care, at periods remote from the primary lesion, symptoms clearly the consequence of the first infection. This question of the cure of syphilis will present itself before you, Gentlemen, especially when the marriage of syphilitic persons is talked of, and you will be consulted for information as to what moment a contaminated individual may marry without danger to his or her partner and the children which may be born of this union. Fournier has treated this question in an able manner, and has shown that generally you cannot authorize such marriage till after a treatment scrupulously followed for three or four years.

Now that we know the duration of the treatment, it remains for us to determine at what time we should commence it. The sooner the better, say Fournier and Mauriac. At the appearance of the first syphilitic manifestations, say Sigmund and Zeissl. I believe that the last advice is the safer and wiser.

The diagnosis of the primitive lesion often presents great difficulties, and unless one is an expert and an experienced one, it is quite easy to confound a hard chancre with ulcerations of quite different nature, and particularly with herpes. These difficulties are often such that we see experts, in doubt, practise inoculations in order to determine the nature of the ulcerations which they have before their eyes. Therefore the practitioner ought to wait for the appearance of the roseola to confirm his diagnosis, and indicate the time for commencement of treatment. When the rash shows itself all his doubts are dissipated, and he may begin the administration of mercury. This delay of a few weeks is a very little thing in comparison with the duration of a treatment which lasts several years, and it has no detrimental influence on the evolution of the disease.

We have already examined two important points in the question of the mercurial treatment of syphilis: the duration of the treatment, and the moment when it should be commenced. It may now be asked if all cases of this disease ought to be treated with mercury and the iodides? My reply is, Certainly; every syphilitic individual ought to undergo the specific treatment. I am well aware that in his remarkable work on the *Natural History of Syphilis*, Diday has shown us that a great many syphilitic patients get well without treatment, and I know also that syphilis, like any other disease, has its mild forms and its severe forms; and, according to the soil in which it is implanted, it may take on a more or less rapid course. But what I am also convinced of is, that we often see very grave tertiary symptoms supervene in persons who have had till then manifestations of syphilis so benign that this disease has passed absolutely unperceived by them. Therefore it will not do to depend altogether on the more or less tardy appearance of the secondary symptoms and their benignity, and abandon the specific medication, and in directing this treatment one ought to think, not so much of the manifestations he has before his eyes, as of those which are likely to appear in the future.

Finally, to terminate these general considerations on the treatment of syphilis, a question remains to be answered: Does the specific treatment cure all the manifestations of venereal disease? Unhappily, no; there is a malignant syphilis with galloping march, of ulcerous form, which resists the best directed specific treatment. Nevertheless these cases are exceptional today; thanks to the hypodermic method we can master the greater number of specific accidents. It is well understood that this treatment will not repair the loss inflicted on the tissues by the presence of certain syphilitic neoplasms, like gummata, and when these have invaded a part of the cerebro-spinal medulla, the lungs, the liver, the pharynx, etc., the specific treatment will be powerless to restore the parts thus destroyed.

These points being duly established, we pass to the study of the syphilitic patient, and we will follow, step by step in their progress, the several manifestations of syphilis. Let us commence by the chancre.

The nature of the chancre being once determined, can we, by cauterization or by excision, prevent the system from undergoing the syphilitic infection and its consequences? Such is the first question we have to solve. From data furnished by the test experiments of Sigmund, Chadzynski Auspitz, and Mauriac, we are warranted in affirming that the most energetic cauterization and even excision made during the first days of the chancre, and before the propagation of this induration to the neighboring glands, does not prevent the development of the secondary symptoms. I am well aware, according to the statistics to which I have re-

[1] Stades de désaccoutumance. Fournier, Leçons cliniques sur la Syphilis. 2d ed. Paris, 1881.

ferred, that successes have been claimed by both cauterization and by excision, but as the failures have always exceeded the successes, it may well be asked if, in the latter cases, an error of diagnosis was not committed? I believe, then, that this question of the excision of the chancre or its thorough cauterization demands new investigation before such treatment can be regarded as efficacious.

The treatment of the syphilitic chancre then consists in local means which have for their object to hasten the cicatrization of the sore; a curative process which, by the way, goes on normally with considerable rapidity. Pomades of calomel and cold cream (one part to four); lotions of chloral (half per cent.); light touches with lunar caustic, and, above all, special care about cleanliness, suffice generally to hasten the cure of the primitive lesion. Whenever the sore becomes deep and anfractuous, and presents a sanious and malignant aspect, you can employ tincture of iodine, or, what is better, iodoform. This latter is veritably a marvellous medicament in the local treatment of syphilis, and since Féréol showed us, in 1868, the happy topical effects of iodoform in chancre, it has daily been put in usage and always with success.

You are well aware that of late years iodoform applications have had a great popularity, and that they occupy to-day the first rank among antiseptic dressings. I know of but one objection to this medicinal agent—its disagreeable odor. Attempts have been made to mask this odor, but none of them have been very successful. It has been employed in pomades, powder, and, better still, in ethereal solution. Berkeley Hill has proposed a very concentrated solution (one part of iodoform to eight of ether). I prefer a very dilute (five per cent.) solution, and I apply it to the genitals by means of a spray atomizer. You can thus cover the most anfractuous parts of the sore with a thin coating of iodoform, and you have often seen in my service the good results which we obtain from these ethereal iodoform sprays in the treatment of venereal sores in the female.

It has been proposed to substitute for iodoform, bisulphide of carbon; but the smell of this compound is quite as disagreeable as that of iodoform, and it is not proved to have any therapeutic advantage over the latter.

When once the chancre is healed, and the roseola makes its appearance, you begin the mercurial treatment, and I have already told you that, in my opinion, the best preparation is the liquor of Van Swieten; and you thus follow the various stages of the disease.

You all know that syphilis evolves by stages presenting characteristic symptoms, and to which has been given the name of secondary period, transition period, and tertiary period. In the secondary period we depend on mercury; in the period of transition we give mercury and iodide of potassium together. A convenient form of administration is the syrup of Gibert, which contains biniodide of mercury with iodide of potassium.

Lastly, in the tertiary period we use iodide of potassium almost exclusively.

There has been much discussion as to the precise time when the iodide should be given. In a recent work, Gougenheim has shown that even in the secondary stages of syphilis iodide of potassium gives good results. Martineau, in opposition to Zeissl, who would give mercury after the iodide, recommends always to precede the iodide treatment by the mercurial, and I believe, judging from my own experience, that his views are sound.

There are certain syphilitic accidents of a stubborn kind encountered in different periods of syphilis, and which resist to a certain extent the mercurial treatment. I refer particularly to the mucous patches that have for their seat the vulva, the pharynx, and even the labial commissure. These patches perpetuate themselves under the least local irritation. As for those of the vulva, you will need to enjoin the utmost care as to cleanliness, and local applications of iodoform and ether, or iodoform ointment, will be required; as for those in the mouth and throat, you must forbid the patient to smoke, and you will have to touch the sores with tincture of iodine or Van Swieten's solution.

The tertiary complications are often very serious, especially when they affect the nervous centres, and urgent measures will be required, such as the administration in large doses of mercury and iodide of potassium. Here we witness the triumph of hypodermic injections of peptonate of mercury, or frictions of mercurial ointment, associated with iodide of potassium; and I know of no more convincing evidence of the efficacy of this kind of treatment than the cures which are obtained in so short a time from cerebral complications so grave that they would have caused the death of the patient in a few days if help had not arrived. Paralytic and meningeal symptoms all disappear as if by enchantment.

When lecturing on the treatment of myelitis, I told you of the difference which exists between the ataxia of syphilitic origin and other affections of the spinal cord due to syphilis; the first being well-nigh incurable, despite the most energetic specific treatment, the second being amenable to such treatment.

Mineral waters have an important place in the treatment of syphilis, and especially the sulphur waters. Numerous discussions have arisen concerning the action of these waters. Some maintain that certain of these waters have anti-syphilitic properties; others that they only make known the fact whether the patient is cured or not of his syphilis; others claim that these waters have only a tonic and stimulant effect. The latter view counts the most adherents, and is undoubtedly the correct view. The favorite resorts for syphilitic patients are the spas of Aulas, Bareges, Luchon, Cauterets, Amelie les-Bains; in a word, the various sulphur springs which abound in the Pyrenees.

I have finished the general treatment of syphilis, but I desire to say a few words about other venereal diseases, viz., the soft chancre and gonorrhœa. Soft chancre requires the same treatment as the infecting chancre. At the same time, under some circumstances, the soft chancre becomes phagedænic, and then it is necessary to employ a very energetic treatment to arrest the spread of the ulceration. Therefore, after failure with perchloride of iron, iodoform, and tincture of iodine, you may have to resort to cauterizations with the hot iron in order to modify the surface of the sore. To all these measures we must add partial baths of 40° C., which, according to Aubert, constitute the most powerful curative agent in simple chancre and its complications. You well

know that the mercurial treatment is contraindicated in phagedæna, and that it is necessary to employ tonics under all their forms.

The treatment of gonorrhœa comprises the treatment of blennorrhagic urethritis, and that of blennorrhagic vaginitis. In the former, several forms are to be distinguished. Either it is a case of acute blennorrhagia, or the disease has become subacute, or has passed on to the chronic stage. In acute blennorrhagia, the most rapidly curative medicine is copaiba. You know that this balsam, which is in reality one of the turpentines, is composed of an essential oil, which is eliminated by the lungs, and a resinous copahivic acid, which is eliminated by the urinary passages, and it is this elimination which is the curative agent in gonorrhœa. But in order to obtain from the copaiba treatment all the benefits which you expect, you must follow certain rules here laid down. Never give copaiba in the first periods of gonorrhœa, when the inflammation is invading the entire urethral mucous membrane, for at this stage it is worse than useless. Rather wait eight, ten, or even twelve days, till this general inflammation has subsided, before giving copaiba. During this period you can give the diuretic infusions, or alkaline solutions, which have a sedative action. Then you can begin with copaiba, which may be given in capsules, dragées, or in some of the numerous anti-blennorrhagic compounds, like the famous potion of Choppart, which contains copaiba with syrup of tolu and essence of peppermint. But in whatever form it may be administered, it is necessary to give it in frequently repeated doses, so that the urine may be always charged with copahivic acid at the time of emission; so when you make use of the capsules, you should order the patient to take six of them a day—one every two hours. You should increase them by one capsule a day till he takes twelve during the twenty-four hours—one capsule every hour during the daytime. This dose should be continued for two days; then you can diminish them by one capsule a day, till the patient comes to take only one in twenty-four hours, at which time the cure ought to be complete.

In subacute urethral blennorrhagia, you can accompany treatment by copaiba with the use of alterative or astringent injections. I assign due weight, Gentlemen, to all the discussions which have arisen relative to the medicinal action of urethral injections, some authorities considering them as beneficial, others as dangerous. I believe that they are both, according to the time when they are employed—dangerous in the inflammatory periods, beneficial in the subacute and chronic stages. You are aware of the multiplicity of these anti-blennorrhagic injections, which may be divided into three groups: first, those that have a modifying action, the type of which are injections containing nitrate of silver; second, astringent injections, such as those of tannin and sulphate of zinc; and, lastly, the parasiticide injections, which are to-day very much in vogue, and although the microbe of blennorrhagia has not been found, it is not the less true that these injections, and in particular those of permanganate of potash, are employed with success in urethritis. I shall only mention the one which I use oftenest myself, of which the formula is as follows:

℞.—Tannin, ... 3 parts.
Glycerine, ... 100 " —M.

In the treatment by urethral injections, it is well to insist upon the directions laid down by Bourgeois. The patient should first be required to urinate; the injection should be retained for several minutes in the urethral canal, and it is necessary that the syringe be in good working order. In my practice, I prefer the syringe of Langlebert. As for chronic gonorrhœa, so-called gleet, it often presents an invincible resistance to every kind of treatment, and nothing is more obstinate than the *goutte militaire*. You must bear in mind that, as pertaining to this incurability, the patient, by his imprudences, plays a more important part even than the disease itself. It is also a noteworthy fact that deep-seated ulcerations or even strictures often keep up this urethral running, and in these cases the use of the sound or of medicated bougies may have a remedial effect.

After the tonic regimen, ferruginous preparations, bromide of potassium, sea-baths, or sulphur waters, will give you more certain curative results than the urethral injections and balsamic preparations, which are here absolutely useless.

I have not spoken to you of the abortive treatment of this disease, and for this reason—I consider it as useless and dangerous. I have been for many years, and am still, physician to a certain association of commercial employés, and I have observed very many cases of gonorrhœa among them, and I have never once witnessed a cure by the injection of strong solutions of nitrate of silver during the first few days of the attack. On the contrary, I have always observed that whenever this treatment was followed, there was an aggravation of the malady. I discard, then, altogether these abortive measures.

The treatment of blennorrhagic vaginitis ought to fulfil the two following conditions: it should modify the surface of the mucous membrane and prevent agglutination of the opposing surfaces. Here vaginal tampons and suppositories are of great utility. Besides the *sachets* and suppositories so generally employed, ointments introduced by special *pomade-depositors*, devised by Terrillon and Auvard, are much in fashion.[1]

Tripier has recommended the employ of clay mixed with glycerine. I myself am in the habit of using a conical wad of finely carded cotton wound rather tightly, having the form of a speculum, which is introduced into the vagina, after being smeared with a suitable pomade.

Apropos of these ointments, there are numerous formulæ, all having for basis substances more or less astringent and antiseptic. Of all these preparations that which seems to me the best, is the mixture proposed by Vidal of Gurgun balsam and lime-water, in the proportion of one part of the former to two of the latter.[2]

[1] The pomade of Terrillon and Auvard is made as follows:
℞.—Tannin, ... 1 part.
Vaseline,
Starch, ... āā 3 parts.—M.
These substances are incorporated into a paste, which is introduced into the vagina by the *pomade-depositor*. This treatment has proved very efficacious.

[2] Gurgun balsam (gurgun oil or wood oil) was first employed, in 1838, in the treatment of gonorrhœa. Vidal employs the following formula:
℞.—Gurgun oil,
Gum arabic, ... āā 1 part
Infus. anisi, ... 10 parts.—M.
Sig.—To be taken in two doses.

When this quantity of lime-water is exceeded, the pomade becomes too thick, and its application on the cone of wadding is rendered more difficult. Using then the preparation above formulated, I smear my tampon with it, and leave it in place in the vagina for twenty-four hours, and I renew this dressing every morning; when removed, the patient should wash out the vagina with a cleansing injection.

Vaginal injections, like urethral injections, require to be taken with certain precautions. The syringe with rubber ball and tubing, called in America the Davidson syringe, is preferable to the hard rubber or glass tubes in common use; or, what is better still in many cases, the fountain syringe with its appurtenances. The terminal canula should give issue to the fluid by lateral orifices.

The formulæ for vaginal injections are too numerous to be mentioned here, and you will find in your special treatises a sufficient number from which to select for any occasion. I shall only refer to chloral injections, which I was the first to recommend. These are now very much in use, and have often a very happy local effect. My usual way of ordering these injections is as follows:

℞.—Hydrate of chloral, . . . 1 part.
Water, ... 10 " —M.

Signa.—Add a tablespoonful of this solution to a quart of cold water for an injection.

Next to these chloral injections, and almost on the same level, I place injections with resorcine. In my study with Callias, of this medicament, I have insisted on the energetic modifying action of this substance on bad ulcerations of the genital organs. Leblond and Fissiaux have just repeated these therapeutical experiments, and with equally good results. I know of but one inconvenience attending these applications of resorcine, it is the high price of the medicament. The injection is made by adding 3ijss of resorcine to a quart of water. Next in importance come the astringent injections, containing tannin, rhatany, oak bark, etc.

I have much more to say respecting the treatment of blennorrhagia, but it is time to bring this long lecture to a close; the indications which I have given will probably meet the greater part of the cases which will occur in your practice.

ORIGINAL ARTICLES.

SUBCUTANEOUS DIVISION OF THE CRUCIAL LIGAMENTS FOR RELIEF OF KNEE ANKYLOSIS.[1]

BY L. McLANE TIFFANY, M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF MARYLAND.

IN common with, I expect, many other medical practitioners, I have experienced not infrequently great difficulty in overcoming the deformity and ankylosis remaining after knee-joint inflammation has subsided, and any operative measure which will, in proper cases, lessen this difficulty is worthy of mention. The procedure named in the title of this paper, division of the crucial ligaments, has been made use of by me with great and immediate benefit to my patient; benefit which, in view of the time which has elapsed since the operation, may be confidently expected to be permanent.

It is not unusual, after that variety of knee-joint inflammation which is denominated white swelling has subsided, to find the articulation left in a more or less ankylosed condition, and the head of the tibia resting more behind the femoral condyles than normal, while there is present at the same time rotation of the limb below the knee, so that the toes point outwards too strongly; the inner condyle of the femur also is overprominent; from which combination of circumstances it results that the function of the limb as a weight-bearing organ of progression is seriously impaired. To restore natural shape and usefulness, division of tendons, of extra-articular bands of fascia, of ligaments; forcible extension under anæsthesia of intra-articular adhesions and bands; shampooing; passive motion, etc., are called into requisition, and with excellent effect.

It is sometimes found, however, that the above means fail to bring about the wished for result, and that, notwithstanding our efforts, the joint remains obstinately misshapen, and more or less stiff.

The deformity of the knee under consideration is far more likely to be met with in children than in adults, and after tendons with extra-articular bands have been severed, the question presents itself as to how much power it is proper to exert in order to rupture forcibly any intra-articular adhesions—the doubtful point being whether the adhesions, the epiphyseal joining, or the bone itself will give way soonest. It is customary to break up adhesions and attempt to restore motion to a knee-joint, not only after inflammation has subsided, but a long time after it has subsided, when, therefore, of necessity the articular surfaces of both tibia and femur have become pretty well settled in their vicious relations to each other. This is a condition of affairs to which neighboring soft parts do not fail to accommodate themselves, for it is a well-known fact that ligaments entering into the construction of a joint will, if the bones are placed in an abnormal position, so adapt themselves to the new attitude as finally to hold the bones in their changed relations, as they, the ligaments, were formerly expected to do in the normal.

There is no good cause why the above line of thought should not apply equally well to both intra- and extra-articular ligaments, and fitting the train of reasoning to the knee, it occurred to me some time since that the crucial ligaments had a good deal to do with the characteristic position which a knee having assumed, retains so sturdily after a severe attack of inflammation, and, as both flexion and extension are limited, that division of these two ligaments would not only permit more motion, but also would enable the tibia to glide forward to its proper position in relation with the femur.

Mauriac recommends as a useful potion in gonorrhœa, the following mixture:

℞.—Gurgun oil, ... 16 parts.
Gum arabic, ... 10 "
Syrup acacia, ... 30 "
Peppermint water, ... 50 " —M.

Sig.—To be taken in three doses.

(Leon Duval, On Gurgun Oil, Thèse de Paris, 1877.)

[1] Read before the Baltimore Acad. of Medicine, Jan. 15, 1884.

In November last a case of knee ankylosis fell into my hands, which I was unwilling to excise, owing to the patient's youth, and not being able to straighten without undue violence, I subjected to division of the crucial ligaments.

In deciding whether a distorted knee should be subjected to the above operation, it is necessary, first of all, that inflammation of and about the joint should have long since passed away, otherwise the necessary manipulation may give rise to recurrence of the original trouble, disastrous suppuration, or what not; furthermore, the patient should be in excellent health with the functions of life well performed. The hamstring muscles, lateral ligaments, and any opposing bands of fascia are then to be divided subcutaneously in the usual way. When the tenotomy punctures have healed, extension under anæsthesia is made, and the operator will be able to recognize that the failure of the joint to still further straighten is due to intra-articular bands.

The amount of power which can be exerted to produce extension must depend upon the surgical acumen of the operator, and a rule in pounds can not be laid down; suffice it to say that a point is reached beyond which the exercise of force will be followed by results prejudicial to the patient's welfare, and this point will be reached earlier in those patients with whom the epiphyseal cartilage persists, than in those whose bones are completely ossified, for of course an epiphysis might be wrenched off by too strong manipulation.

Further forcible extension being inexpedient and the deformity continuing, division of the crucial ligaments is indicated and may be done as follows: The patient lies on the back, the affected limb is held steadily in extension so as to render tense the anterior crucial ligament; the tenotome is entered to the inner side of the ligamentum patellæ, a quarter of an inch above the articular surface of the tibia, and carried backwards and outwards so as to pass between the tibial spine and the external condyle of the femur below the ligament (crucial). The flat of the blade is towards the articular surface of the tibia, the back towards the ligamentum patellæ, the edge towards the spine, after entering the joint. The cutting edge of the knife is now to be carried across the joint from side to side, the edge being directed so as to pass over the spine, and divides the anterior crucial ligament just above its attachment to the tibia; the posterior crucial will probably also be divided, but as it lies further from the skin puncture it is well to reverse the edge of the tenotome, without withdrawal, pass it more deeply into the joint, and carry it from the internal to the external condyle, retracing the path already travelled.

Before entering the knife, the skin should be drawn upwards that the wound may be valvular and air less likely to gain admission to the joint. The tenotomy wound is to be treated as usual. If division of the ligaments has been accomplished, the limb can at once be well extended; the tibia is felt to glide forward upon the condyles to occupy almost if not quite the usual situation, the posterior projection disappears, and the eversion of the foot is lessened. A proper retentive apparatus is to be applied—I use plaster of Paris—and the knee held in its new position until all likelihood of inflammation is past, when passive motion is to be commenced. Inasmuch as the affected limb, from long-continued non-use, is usually not well developed, friction, electricity, etc., can be used with advantage.

Certain practical points in the operation described above present themselves and claim attention: one is the depth to which the knife must be entered before attempting to cut the ligaments; this will of course depend upon the size of the knee demanding treatment; the case related hereafter required that the tenotome be entered one inch and three-quarters. Lately, when practising the operation upon an adult male subject in the dissecting-room, I found that the cutting edge of the knife had to be carried two inches and a half below the skin surface before the crucial ligaments could be severed; here, of course, the joint was healthy. It is wise, I think, that the tenotome should have a blade about three inches long, of which not less than one inch should have a cutting edge, the better to divide both ligaments at one time; also a long and slender point is not entirely free from chance of fracture in an ankylosed knee-joint, and it is well to have the end rounded or chisel-shaped with the corners cut off, furnished, however, with a good terminal edge.

CASE.—A. W., female, aged 11 years, came under my care November 12th. She desired to have her left leg rendered more serviceable. At the age of two years she had an inflammation of the left knee, after which the joint remained flexed nearly at a right angle, so that walking on the limb was not possible. She has always used a crutch. Examination shows the leg flexed on the thigh as stated, the inner condyle of the femur very prominent, the foot rotated outwards strongly, and the head of the tibia displaced backwards to a marked degree. The thigh showed a deeply depressed cicatrice presumptively connected with the former knee disease. Both thigh and leg were less developed than upon the right side, owing, perhaps to disuse, perhaps to inflammatory changes in the epiphyseal cartilages. I divided tendons, fascia, etc., and put a splint on the limb until the tenotomy punctures had healed. Extension to a certain point was then possible, but strong resistance was, beyond this, experienced. No tense structures could be felt, and so it was inferred that the crucial ligaments required cutting. This operation was then at once done, after which the limb could be straightened and the tibia-head advanced to its proper position upon the femoral condyles. The puncture was covered with a piece of absorbent cotton, the whole limb enveloped in cotton wadding and encased in a plaster splint. No pain or constitutional disturbance ensued; examination at the end of one week showed the puncture healed. At the end of three weeks, passive motion was commenced, and the patient is now gaining both strength and motion. The tibia has not returned to its former position behind the femur, the sole of the foot rests on the floor, and the limb bears weight.

THE SANITARY CONTROL OF THE FOOD SUPPLY.[1]

BY WILLIAM K. NEWTON, M.D.,
HEALTH OFFICER OF PATERSON, N. J.

THERE is no one subject more intimately connected with our every-day life, and about which so much has been written and published the past few years, as the condition of our food supply. The columns of medical, sanitary, and chemical journals, and the reports of State and local boards of health, have been crowded with essays on food adulteration and plans for checking it; and the popular papers have teemed with the horrors of the subject, each trying to vie with the other in furnishing the latest meal of adulterated articles, till, if we believe the sensational stories of these alarmists, we wonder why there are any people left to tell the tale. The amount of evidence bearing on food adulteration at our command to-day is enormous.

First, let us see what is the prevalence and what the proportion of adulterated food, and then note the effect of prosecution and investigation thereon.

As to Continental Europe we can say but little, for the records are so scattered, and the laws so multifarious, that we have but a trifle to offer. In France, to judge from the published reports, chemists note articles as good, bad, passable, not injurious, and injurious. Thus, in March, 1883, out of 1118 articles examined at the Paris laboratory, 271 were returned as good, 231 as passable, 616 as bad, 545 of which were "not injurious," and 71 "injurious." It is difficult to tell just what is meant by these terms, and as we are not informed which are pure and which adulterated, no opinion can be formed. Wines form by far the largest number of articles examined, and, from the report, we judge that the Parisians get very little pure wine. Of 257 samples of milk, 26 are returned as good, 116 as passable, and 115 as bad, but not injurious.

GREAT BRITAIN.

Year.	Number analyzed.	Per cent. adulterated.
1875–6	15,939	18.10.
1877	11,943	17.70.
1878	15,107	16.58.
1879	17,574	17.25.
1880	17,919	17.47.
1881	17,363	16.56.
1882	14,900	16.50.

These totals do not represent foods exclusively, for drugs, wines, spirits, and beer are included; nor do they indicate the state of the food for the whole of Great Britain, for, as before stated, in many parts of the country no work is done under the Act.

It will be seen by glancing at the figures that five years' work, from 1877 to 1882, has only reduced the amount of adulteration 1.2 per cent. When it is remembered that a vigorous prosecution has been kept up, we are compelled to acknowledge that the results are not very encouraging.

Selecting a few articles from the list for purposes of comparison, we find that of the samples of milk analyzed the per cent. adulterated varied from 26 in 1877, to 20.35 in 1882. Butter, including oleomargarine sold for butter, 12 to 15 per cent.; groceries, 13 to 10 per cent.; bread and flour, 6.34 to 4.32 per cent. Canada shows by far the best results obtained by any country, and the reduction in the amount of adulteration has been made by but little prosecution; the only form of punishment indulged in is the publication of the names of the dealers in impure articles. In 1876, when the work was begun, 51.66 per cent. of the articles examined were adulterated; in 1882 this figure is reduced to 25.66, showing an improvement of a little over 25 per cent.

As there has been little or no prosecution in the United States under the food laws, but little can be recorded as having been done in the way of a reduction of the percentage of adulteration. In New York and other cities, and in New Jersey, the sale of impure milk has been markedly reduced, but there is still much work to do. If we look over the reports of the analysts of New York, New Jersey, Massachusetts, Michigan and other States, we obtain a fair idea of the prevalence of sophistication in this country. We find that the staple articles, such as are used in the average household, suffer adulteration about as follows: Spices and condiments, 66 per cent.; ground coffee, 45 per cent.; tea, 43 per cent.; sugar, the higher grades rarely, the lower grades 20 per cent.; syrup, 50 per cent.; milk, when not inspected, 50 per cent.; flour, none; bread, about 2 per cent.; cream of tartar and baking powders, 44 per cent.; butter, 40 per cent. (other fats substituted); vinegar, seldom adulterated, but rarely cider vinegar; olive oil, 60 per cent.

Spices and condiments are adulterated with exhausted spices, ground cereals, flour, buckwheat hulls; coffee with chicory, rye, and other cereals; tea with exhausted leaves, leaves of other plants, damaged teas, coated to improve looks; sugar with grape sugar; syrup with grape sugar, in many cases all glucose; milk with water, alkaline salts to neutralize acidity, preservatives, and is often skimmed; bread, alum added to increase whiteness, rarely used in this country; cream of tartar and baking powders, gypsum, starches, and "fillers," to increase bulk; butter, other fats substituted for it and adulterated with foreign fats; vinegar, rarely adulterated, but often not fruit vinegar; olive oil, peanut and cotton-seed oil.

It will be noted, after glancing over this list, that the simple articles in every-day use are never adulterated with injurious substances, and the evidence thus far offered indorses the statement made in the first part of this paper, that adulteration is a sin against the pocket and extremely rarely against health.

A group of substances which may be classed together and which, strictly speaking, are not adulterations, but are often used for the purpose of sophistication, will now be considered.

Oleomargarine.—It is difficult to say whether this may be put in the category of articles to be placed under the watch-care of sanitary officials. Some

[1] Condensed from a paper read before the American Public Health Association at Detroit, November 14, 1883.

have held that there is danger of animal parasites or diseases being introduced into the economy by the use of this article, but the best authorities deny this statement. Personally, I am of the opinion that it should be classed with the commercial frauds, but that its manufacture should be watched carefully by health officers. You are so familiar with the process of manufacture that it does not seem necessary for me to go into detail. Suffice it to say, that the aim of the maker is to produce a sweet and merchantable article, as any rancidity would interfere with its sale. This fact insures the public against any putrid or ill-smelling fat being used. The quantity of this material sold and used as food in the United States is enormous. We may form an idea of the extent of the business when we know that three factories in New York State turn out not less than 4500 tons a year, and there are some five or six more factories in the country. I venture to state that a very small portion of this is sold to the consumer for what it really is.

We must recognize the necessity for some legal control over this trade, and dealers should be compelled to sell the article on its merits, and not fraudulently. The enforcement of such a law does not belong to health boards, however.

"Lard Cheese" and "Lardine."—An ingenious New Yorker has discovered that he can take milk robbed of its cream, and by the introduction of a foreign fat produce a cheese equal to an honest cream cheese. Lard and oleomargarine oil have been used in this process, and the resulting material is known as "lard cheese."

"Lardine" is an artificial butter made in nearly the same way. Now, if these articles were sold to the public on their true merits, no one would complain; but such is rarely the case, and if persons are thus defrauded, it may be argued that legal protection to the innocent purchaser is demanded.

Glucose (*Grape Sugar*).—It is estimated that ten pounds of glucose per capita is made and sold each year in the United States; and we naturally ask, What becomes of it? No one ever heard of a person asking for the substance at a grocery store. Yet it is sold and consumed somewhere. We can account for a large percentage of the substance in the syrups, strained honey, confections, and in the lower grades of sugar.

Attempts have been made to check or prohibit the sale of this article, which, as Dr. Squibb has it, "marks the progression of the age." The legislators of New Jersey passed a law in 1881 requiring that the manufacturers of sugar and syrup who shall mix therewith any glucose or grape sugar, must mark the package with the word "adulterated," under a penalty of $500. This law came before Governor Ludlow for his signature, which he refused to affix. His veto message will bear quoting here, for it answers the question as to whether the substance shall be considered as injurious or not. He says: "The manufacture of glucose or corn sugar is an enterprise yet in its infancy; it will, if successful, result in the utilization of the corn crop of the country, the increase of the sugar supply, and the consequent employment of a large amount of capital and labor. Scientists of acknowledged ability and integrity have declared it to be a healthful article of food, and there is no reason why the result of its mixture with cane sugar should be marked 'adulterated,' as if it were a debasement or pollution." The Legislature was satisfied with the Governor's explanation, and did not enact the law.

Frequent statements have been made that the sulphuric acid used in its manufacture has been found in large and poisonous quantities in the glucose syrups. This is either a perversion of facts or an exaggeration. It is true that sulphuric acid is employed in the conversion of starch into grape sugar, but the acid is afterwards neutralized by means of milk of lime. If any acid exists in the syrup, it is either in combination with the lime or free and in very small quantities, a condition strenuously avoided by the manufacturer.

It may be said without fear of contradiction that glucose may be considered a harmless article of food.

As to the use of this article as an adulterant, I hold that it does not come under the jurisdiction of health officers.

Canned Foods.—There is sufficient evidence to warrant us in asserting that fruits, vegetables, and meats preserved in tin need our attention. Many cases of acute poisoning of greater or less severity have been reported by competent observers. It has been proved that some fruits and vegetables act upon the tin or lead, and enough of these metals is dissolved to cause serious illness. This is especially true of the very acid fruits, such as apples, cherries, and vegetables like tomatoes.

One case has come under my notice where two persons were seized with an attack of vomiting, purging, and cramps after the ingestion of apples preserved in tin. I was fortunate enough to obtain the can and the remainder of the fruit. The interior of the can presented a crystalline appearance, such as is described by Wood and others who have investigated the subject. The fruit was acid in reaction, and analysis revealed tin in considerable quantities.

It has been suggested that only old and imperfectly prepared fruits and vegetables cause trouble, and that to insure the freshness of the article the year of canning should be stamped on the package. This subject needs thorough investigation.

As to illness being caused by corned beef and other meats in cans, I can say that I have seen two cases, but the trouble seemed to be due to imperfect preservation, as the meat in both cases was partially rotten. Both cans were what is known in the trade as "swelled-head," that is, the ends of the can bulged out by air or gases in the can; hence these cases cannot be cited as being caused by canned meats by themselves.

Preservatives.—I wish to call attention to the use of preservatives, as the custom seems to be increasing, and the subject should be thoroughly studied before a competent opinion can be formed as to the advisability of their employment. Those which I have examined have consisted of salicylic acid, either alone or combined with soda; alkaline carbonates; potassium nitrate; and borax or boric

acid. These are extensively advertised in glowing language and with the usual accompanying certificates from chemists or physicians, and meet with ready sale. Many fanciful names are given to the compounds, and each is claimed to be "positively harmless."

My own opinion is that their use should be discountenanced by sanitarians, for the mere fact that a certain chemical combination will check fermentation or putrefaction outside of the body, leads us to believe that digestion will be impaired or impeded. This I have sought to prove in an imperfect way by treating milk with a preservative and then attempting artificial digestion. Digestion was proved to be interfered with, or checked altogether.

Thus far we have been discussing certain laws and duties relating to the food supply with which health boards may or may not properly concern themselves. Your attention is now called to a group of foods, and the trades connected therewith, which need the constant surveillance of sanitary officers. I refer to bread, milk, and meat, and the trades of baker, milk-seller, and butcher, each one of which should receive the closest attention of health officers. The importance of this branch of our subject is so evident that I shall go somewhat into detail in pointing out the line of investigation necessary.

Bread.—The amount of adulterated bread sold in the United States is very small, certainly not one per cent. of the quantity used. Alum is sometimes used to make bread appear white, but it is not a common practice. It may, by prolonged use, cause indigestion, and of course its use should be checked. But the health officers' duties do not end with the mere examination of bread for alum; he should carry on his inspection further, and into the bake-shop, notice the condition and surroundings of the place, and insist that there should be cleanliness in every branch of the business.

Bake-shops are usually located in cellars and are very often damp, dirty, and foul-smelling, and if a person with a sensitive stomach should visit many of them, I am of the opinion that the demand for home-made bread would be increased.

The very occupation of baker is apt to cause certain diseases of the skin of the hands, and although no illness may be caused by it, it is not pleasant to think of our bread containing the scales or scabs from eczema.

To give a leaf from the history of a few visits to bake-shops may interest you and impress upon your minds the importance of the sanitary control of such places.

Most of the places visited were damp, dark cellars, where artificial light is constantly used. In one place we found the cat and dog asleep in the kneading-trough, fowls running around and perching on the various utensils, and a general air of filth and lack of thrift. In one shop the kneading-trough was connected with the sewer by means of an untrapped waste-pipe; in another the soil-pipe had burst and the floor was flooded with liquid filth. The baker said that "that always happened after a rain-storm." I have seen a baker mixing his bread with hand and arm covered with the eruption of eczema. He said that "the doctor told him the dough was good for the disease." But we would say that the quality of the bread was not improved thereby.

The custom of using bake-shops for sleeping-rooms is very common and must be discountenanced.

I would insist, then, on the necessity of frequent inspections of bake-houses, in order that their cleanliness should be insured.

Milk.—When we consider that milk is universally used, and that it constitutes almost exclusively the diet of children at that time of life when they are least able to resist any interference with the purity of their food, we are forced to the conclusion that strict measures should be adopted by every health authority to insure that condition of the supply necessary for good health. It is pleasant and encouraging to know that this is acknowledged by most sanitary officers, and that more or less efficient work is done by a great number of health boards to check the sale of impure milk. But the mere inspection of milk for the purpose of detecting adulteration, although most commendable, does not go far enough and is not in itself sufficient. The watchfulness of health officers should go much further and should extend to the dairies from which the supply may come; this I shall insist on, and shall state cogent reasons for demanding it.

We are in a position to state that the adulteration of milk is confined almost exclusively to the addition of water, preservatives and alkalies, and to the abstraction of cream. These adulterants are not in themselves injurious to health, but when we know that the nutrition of an infant is seriously interfered with by the impoverishment of the milk given it, we see wherein harm may be done.

Beside checking the sale of adulterated and impoverished milk, the inspector should be on the lookout for milk from dangerous sources, some of which I shall now indicate.

Milk produced by improper feeding: Distillery waste, and sometimes beer grains, produce a quality of milk of low nutritive powers and dangerous to infants.

Colostrum: The milk from cows soon after calving should not be sold. It has often produced intestinal troubles in children.

Cattle improperly cared for: Cattle improperly housed and cared for, especially those kept in cities, need close watching, and the stables should be frequently inspected.

Milk from diseased cattle: Milk from diseased cows is especially dangerous, and we may assert that the use of this article from tuberculous cows is very hazardous. Sufficient evidence has been offered by good and careful authorities to prove that there is a possibility of the transmission of tuberculosis by means of the milk, and phthisis is quite a common disease among milch cows when crowded in ill-ventilated stables. Fortunately, the secretion of milk is checked during many of the acute cattle diseases, but there is the risk of carelessness on the part of dairymen; hence inspectors should be always on the alert.

Finally, there is the great danger of the transmission of contagious diseases—the milk acting as the carrier. This fact has been carefully noted in England, and many epidemics of typhoid fever, scarlet fever, and diphtheria have been traced to the dairyman's house.

Mr. Ernest Hart, of London, has epitomized about all that is known on this subject in an article read by him before the International Medical Congress in 1881. He sums up as follows:

"The number of epidemics of typhoid fever recorded in the abstract as due to milk is 50; of scarlatina, 15; of diphtheria, 7. The total number of cases occurring during the epidemics traced to the use of infected milk may be recorded in round numbers as 3500 of typhoid fever, 800 of scarlet fever, and 500 of diphtheria. When it is remembered that barely ten years ago we were utterly ignorant of milk being a carrier of infection, and that consequently these epidemics have all occurred within one short decade, it will be seen how vitally important is the safe guarding of our milk supplies from contamination."

The number of *The Lancet* for October, 1883, No. 33, p. 652, records an epidemic of typhoid fever at St. Pancras, the details of the investigation being given by Mr. Murphy, Medical Officer. There were 431 cases in 276 houses, and 220 cases were traced back to a dairy which supplied most of the houses with milk.

We can easily account for the method of transmission in many cases. Thus, a can of milk—a fluid especially apt to absorb, and take up impurities from the surrounding air—may have been exposed to the emanations from a case of scarlet fever, or the can wiped out with a soiled towel or cloth from the patient. The cases of typhoid fever traced to dairies have, as a rule, been accounted for by the contaminated water which has been used to dilute the milk or wash out the cans.

That the causes of the epidemics of some zymotic diseases have not been traced out in this country, is probably due to want of care on the part of our sanitary officials.

I shall ask you now to consider a plan for a control of the milk supply, which I think should be followed by all sanitary officials. A registry of the milk-dealers should be kept, backed up by the law, if necessary, and this should include the name of the dealer, the location of the farm, the amount of milk sold daily, and after inspection of the farm and the milk, notes should be added as to the quality of the milk, the condition of the farm-yards and the cattle, the breed of the herd, and the kind, quality, and quantity of feed given. If this plan is followed out, it will not be long before a complete sanitary control can be kept over the milk supply. We are working on this plan in Paterson, but it is too early to arrive at results. So far it has worked well.

Meat Supply.—Most of our larger cities provide for meat inspection in their markets, but it begins and ends with the inspection of the meat actually exposed for sale, and as a rule only meagre, putrid, and immature meat is condemned. This system is defective in that it does not provide for the surveillance of slaughter houses, and the examination of all cattle before or immediately after killing, and before the meat is offered for sale. In many of our cities the cattle are brought to the butcher by railroad after a long journey; they arrive in an exhausted and feverish condition, and are not fit to be used as food. In our smaller towns and villages, only the very young or very old cattle are slaughtered for local use. Not only are the cattle actually diseased at the time of killing, but the meat itself, by improper treatment, may act as a home for dangerous germs. Mr. Francis Vacher, of Birkenhead, in an able paper read before the International Medical Congress, refers to several ways in which meat might spread diseases, thus, it might itself be in a pathological condition, or serve as a medium in which disease germs were nourished and multiplied, or it might serve as a nidus in which such germs rested. Thus, a specific disease may be communicated to man by the ingestion of meat tainted with splenic fever, or foot-and-mouth disease, or from a tuberculous animal.

We are warranted, then, in claiming that meat inspection should include an examination made by competent persons before death, or, before the meat shall be exposed for sale in the markets; this plan may require the services of a skilled veterinarian, but it seems to me essential.

As many of our towns are now supplied almost entirely with meat killed and dressed in the West, and brought to market in refrigerator cars, this system of inspection will perhaps have to be followed by officials appointed by the general government, for it would not be equitable to burden a city with work which does not concern it.

A CASE OF PAGET'S DISEASE OF THE NIPPLE AND AREOLA.

By G. E. DE SCHWEINITZ, M.D.

In 1874, Sir James Paget published his now wellnigh classical paper, "On Disease of the Mammary Areola preceding Cancer." Since that time numerous publications upon the subject have appeared, especially abroad, but also to a lesser extent in this country. The affection, variously designated as "Eczema of the nipple and areola," "Paget's disease of the nipple," and more recently "Malignant papillary dermatitis," has been the subject of clinical study by Morris, Lawson, Napier, Heywood Smith, Forrest, Munro, McNaughton Jones, Savory, Chambers, Welply in Great Britain, Busch in Germany, and C. B. Porter, Sherwell, S. W. Gross, and Duhring in this country. The pathological histology of the disease has been especially investigated by Mr. Butlin, Dr. Thin, Dr. Goodhardt abroad, and by Dr. Cabot in this country.

It is the object of this paper to place another instance upon record, for, as is justly remarked by Dr. Thin, "opinions regarding the exact nature of this class of cases will probably vary considerably until full details regarding a considerable number of them have been published." The patient whose case

forms the subject of the present sketch was under the care of Prof. John Ashhurst, in the University Hospital, and it was by his kind permission that I was permitted to examine the diseased nipple and areola, together with the cancerous breast which lay beneath them.

Mrs. B., aged 52, married, and the mother of children. Her father and mother were killed by an accident; of the two brothers and two sisters who formed the remainder of the family, all are living and healthy. She has no knowledge of her grandparents. Her own health has usually been good. Six years ago she fell from a step-ladder and considerably bruised the right breast and right side of the body, and was troubled for some time afterwards with shooting pains in this region. About six months after the accident, she noticed a crust forming upon the nipple, which constantly reformed after removal. This crust grew larger and spread gradually to the areola, while the nipple began to retract. A little more than a year ago she first began to perceive that a lump was forming in the breast, and that for three months preceding its appearance there were marked increase and extension of the disease of the nipple and areola.

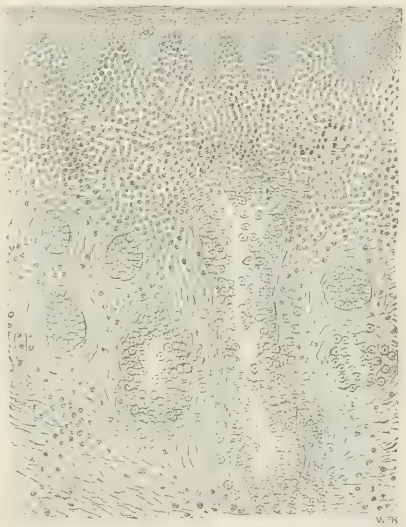
Such is the history obtained from the woman at the time she presented herself for operation. The gross appearances of the breast at this time were as follows: The gland was enlarged and thickened, and its weight markedly increased. The nipple was completely retracted, and the areola and the skin around it, over an irregularly oblong patch about three inches by two inches in extent, of a deep-red color, with a peculiar glossy appearance, which fully justified Sir James Paget's description of these cases in its resemblance to the glans penis when affected by acute balanitis. The subcutaneous veins over the upper part of the breast were enlarged. The axillary glands were involved to a moderate extent.[1]

Microscopic Appearances.—The epidermis, especially that overlying the nipple and areola, was much changed and at times disintegrated. Here and there narrow strips of the horny layer remained, but in some places it had entirely disappeared. The outlines of the rete mucosum were often but poorly defined between the remnants of the horny layer above and the dense small-cell infiltration below, and in spots its entire absence was noted, allowing the papillary layer of the cutis to stand out in small finger-like prolongations from the edge of the section. This latter fact, however, was probably due to faulty preparation or careless handling of the section.

In the more diseased parts, changes of a retrograde nature were visible; viz., swelling of the nucleus, its disappearance, and the vacuolated cell-substance as it has already been described by Dr. Thin. The mucous layer of the epidermis had further undergone proliferation and extension downwards. This appearance was most marked in such sections as included both healthy and diseased tissue, where the descent of the rete, as it were, showed in marked contrast to its normal outlines and thickness in the healthy portion. In some sections there were present a few cell-nests, giving the appearance of an epithelioma, a condition also noted by Mr. Butlin; but as this only occurred in those cuts which were made transversely or obliquely, I think it not improbable that they were due to the method of cutting the sections, for precisely similar appearances can be obtained by making similar sections of healthy skin.

The corium, and to a less extent the subcutaneous tissue, was densely infiltrated with small round cells (leucocytes). So dense was this infiltration, that in the upper parts of the corium, in the immediate neighborhood of the nipple, it entirely substituted the normally present tissue. The papillary layer of the cutis, while it was in no instance entirely destroyed, was displaced, as it were, by this small round-cell infiltration. The disposition of these cells was at times peculiar, being often uniform, sometimes gathered together in round nest-like masses separated by intervals of non-infiltrated tissue, and here and there they were crossed by spindle-cells and fibre-cells, giving somewhat the appearance of young cicatricial tissue. Passing to the deeper layers of the corium (pars reticularis) and the subcutaneous tissue, here also the round cells were present to a less degree than above. Even in the subcutaneous tissue now and then an

FIG. 1.

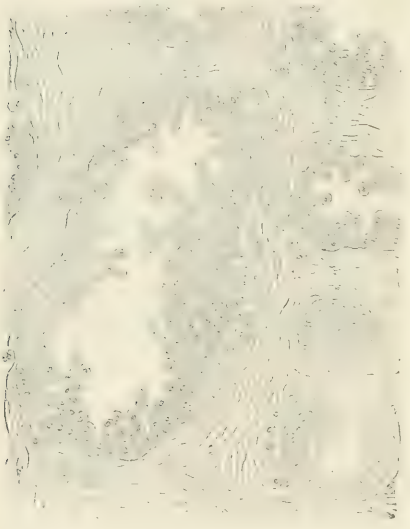


Section through the nipple, showing infiltration of the cutis. Dilated ducts with their epithelium proliferating are also seen. The epidermis is partly diagrammatic, and does not represent its appearance as described in the text.

[1] A chromo-lithograph of this case is to be seen in the International Encyclopedia of Surgery, vol. iv. p. 634.

isolated mass of round cells similar to the ones just described was noted, and usually in intimate relationship to a bloodvessel. The bloodvessels of the corium were numerous and often dilated. The small round cells are no doubt for the most part emigration corpuscles, and not, I think, as has been suggested, derived from a disintegration of the cells of the rete and an escape of their nuclei. The most prominent features of the subcutaneous tissue were the distention of the lymph-spaces, and the fact that they were in many places filled with epithelial cells; together producing a picture quite indistinguishable from any section of ordinary spheroidal-celled carcinoma. This arrangement could be seen not only in the deeper layers of the subcutaneous connective tissue, but also higher up, where it joined the lower layer of the corium, and even up into this tissue almost to its union with the epidermis. Examination of the lactiferous ducts revealed their epithelium in a high state of proliferation, and no longer of the shape natural to the part. The proliferating epithelium was often seen escaping from the ducts and pouring out into the surrounding connective tissue, and here arranging itself in the spaces before

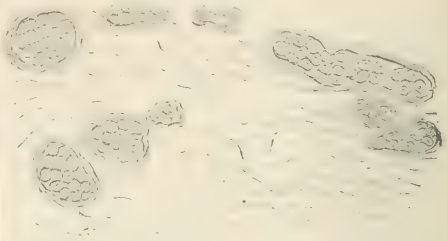
FIG. 2.



Cross section of the nipple, showing the dilated ducts with proliferating epithelium pouring out into connective tissue, and arranging itself in the spaces.

described. This choking up of the lumen of the ducts and proliferation of their epithelium, could be traced from their outlets downwards into the hardened nodules of the breast. Sections of these nodules showed the following structure: In the younger parts the acini were dilated and gradually filling with epithelium Finally they coalesced and formed a large carcinomatous alveolus. Alveoli of this nature having become superdistended with epithelium, the epithelium escaped into the connective tissue and new cancer cylinders were thus formed, lying in the distended connective-tissue spaces, precisely as had occurred in the nipple.

FIG. 3.



Nests of spheroidal epithelial cells from the nodules of the breast tumor.

The type and character of the epithelium were preserved throughout; spheroidal-shaped cells with outlines more or less perfectly defined and small nuclei.

The following propositions represent a brief recapitulation of the more important points in the foregoing description:

1. A dermatitis characterized by a proliferation, and at times degeneration of the mucous layer of the skin, and a dense small round-cell infiltration especially of the upper part of the cutis, substituting the normally present tissue of the papillary layer.

2. Proliferation of the epithelium of the galactophorous ducts and its passage out into the surrounding connective tissue of the nipple.

3. Distention of the lymph-spaces of the subcutaneous connective and their occupancy by epithelial cells similar in character to those found in the distended ducts.

4. A similar epithelial proliferation in the gland-tissue of the breast, and the formation of a spheroidal-celled carcinoma.

From this *résumé* it will be seen that these observations are of interest because they go to confirm similar facts noted by other investigators. The question whether this dermatitis is the primary disease or whether it is produced, as Dr. Thin suggests, "by a destroying agent which extends from the mouths of the lactiferous ducts into the surrounding papillary layer," the poison being the cancerous epithelium of these ducts as distinguished from their normal epithelium, is still an open one. The clinical history of this case, which shows that the disease of the areola and nipple existed for nearly five years before the appearance of the tumor of the breast, would rather, I think, incline to the correctness of the former view, although Dr. Thin does not believe this objection to his view to be a valid one. Certainly this case, taken in connection with

other reported cases, would indicate the correctness of the following propositions:

1. The malignancy or malignant tendency of the disease.

2. The tendency of the changed epithelium of the ducts to travel downward and produce carcinoma of the breast.

3. The propriety of excising a breast thus affected before any tumor of the gland tissue itself can be detected.

MEDICAL PROGRESS.

Inhalations of Carbonic Acid in Whooping-cough.—M. Campardon has recently experimented with this treatment in the case of a child of ten years of age, sick for five months. The carbonic acid gas used was obtained from an apparatus for making seltzer-water, and was slowly inhaled through a rubber tube placed at the nasal orifices. After a few inhalations the cure was complete. M. Campardon insists that the gas should always be charged with vapor of water. The method is very cheap, and may be commonly used on this account.

M. Constantin Paul employs this gas in his service to give relief from the pains accompanying certain affections of the respiratory apparatus, particularly tuberculous laryngitis. He obtains a very prompt and marked relief.

M. Moutard-Martin advises compressed air in pertussis. It does not cure the disease, but it diminishes the number of paroxysms, and this diminution enables the patient to take food more readily.

M. Dujardin-Beaumetz states that while the actions of compressed air and carbonic acid gas are entirely different, the effects are very similar. Compressed air acts like oxygen, by controlling vomiting; the carbonic acid gas acts as an analgesic, suppressing the laryngeal reflex which brings on the paroxysms.—*Revue de Thérap.*, December 15, 1883.

Intestinal Tuberculosis from Swallowing Tuberculous Sputa.—Mosler reports the case of an almost idiotic patient, who insisted on swallowing his sputum. Two days after the commencement of an attack of specific bronchitis he began to have diarrhœa and an intestinal colic, which continued until his death, about the eighth day. Tubercles were found in the lungs; of the other organs only the intestines were affected, the jejunum being most markedly tuberculous.

Mosler attributes the intestinal tuberculosis to the fact that the sputa were swallowed. He has not been able to verify this by experiments on animals, but he has caused violent inflammation of the stomach and small intestine by feeding them with tuberculous sputa and masses.—*Journ. de Méd. de Paris*, December 22, 1883.

Alimentation by Meat-juice.—At a recent meeting of the Société de Thérapeutique, M. Brame read a note on the preparation and use of meat-juice flavored with orange-flower water.

M. Dujardin-Beaumetz gave the following as a method for disguising the disagreeable odor and taste of powdered meat: Two ladlefuls of meat-powder and the same quantity of syrup of punch are thoroughly mixed, when a variable quantity of cold milk is added, according as the patient desires a more or less liquid preparation. When the taste of rum becomes disagreeable, syrup of wild cherry may be added.

M. Blachez thinks that meat-juice contains only a small quantity of the active substances of the meat. When meat-powder cannot be obtained, crude meat may be substituted for it; this may be prepared so as to do away with all disagreeable qualities. It should be chopped finely, the pieces rolled in flour, and then butter is added; these pieces are then thrown into the soup.

M. Catillon recommends the addition of Madeira wine to the powdered meat, especially if it is desirable that only a small quantity of alcohol be given to the patient.—*Revue de Thérap.*, December 15, 1883.

The Presence of Phthisis in Prisoners.—Whilst the mortality in the Prussian prisons in 1878–79 and 1880–81 averaged 30.6 per cent.—amongst a people in good hygienic circumstances—there was an average death-rate in Prussia in 1876–1880 of 25.5 per 1000. Among the people of the mountainous districts the average was 10.54 per 1000, and amongst inhabitants of the lower country 21.4 per 1000. Of all diseases, phthisis occupied the first place; so that the death-rate of phthisis amounted to 40 or 50 per cent. of the whole number of deaths. In the majority of cases the phthisis was acquired in the prisons. As a cause for this, the insufficiency of disinfection stands first. Prominent, also, as a cause, is the custom of putting prisoners together in sleep- and work-rooms.

The excessive mortality of phthisis must be accounted for by the universal presence of the bacilli or their transportation by articles of clothing; the prison life is also favorable to the development of the bacilli, on account of the lowering of the vital forces.—*Centralbl. f. klin. Med.*, December 8, 1883.

HYDATID CYSTS OF THE ORBIT.—M. Chauvel recently read before the Société de Chirurgie a report on a paper by M. DIEU relative to the history of this affection. The paper is based on one personal observation.

The patient was an Arab woman, who had had exophthalmia for a year. The eye was immovable, and looked upward and outward. Vision was abolished, and there was intense venous congestion of the papilla. Puncture of the eye gave issue to a clear liquid, vision was reëstablished, and the patient left the hospital, but the strabismus continued, and atrophy of the papilla having ensued, vision was lost.

M. Dieu draws the following conclusions: Hydatid cysts of the orbit are analogous to those of other regions, and the hooklets are easily found in the liquid.

They are more frequent in males than in females, the proportion of collected cases being eighteen to six.

Two-thirds of all cases have occurred before the age of twenty-one years.

The symptoms are the same as those of encysted tumors. The pains may be very acute, and the symptoms of surrounding inflammation more pronounced than with other benign tumors.

The course of the affection is generally slow, though sometimes it is rapid.

The diagnosis is established by palpation, when the cyst is accessible, by exploratory puncture and chemical and microscopical examination of the liquid.

The prognosis is serious; for, after operation, the eye has been lost six times, and vision has been lost or diminished in twelve cases. Of twenty-six cases there were two deaths. The treatment consists in puncture, followed by incision, and drainage.—*Revue de Thérap.*, December 15, 1883.

ADENOID VEGETATIONS OF THE PHARYNX.—DR. K. DÉHIO concludes an article on this subject as follows:

1. The adenoid vegetations which are frequently developed in the naso-pharyngeal cavity of a child are shown externally by the peculiar appearance of the face; this peculiarity consists in permanent opening of the buccal cavity, lengthening of the face, feebleness of the jaws, projection of the cheek bones, and projection forward of the superior maxillary region.

2. Anatomically, this modification consists essentially in a deformity of the superior maxilla. This bone is flattened transversely in its buccal part. The alveolodental curve is deformed both in its form and dimensions. The lateral parts are sometimes diminished to one-half their transverse diameter. *Per contra*, the depth of the palatine vault is increased. In this way, the vault is narrowed and deepened.

3. The teeth, on the contrary, preserve their volume, and in this manner they are ranged irregularly before and behind the dental arch. More often they project forward, *en masse*, producing a considerable projection of the whole anterior range, so that the front teeth project over the lower lip.

4. This peculiar conformation of the palatine vault and the dental arch has been variously interpreted. An ethnological signification has been generally given to it, some authorities regarding it as evidence of superiority, others of inferiority of race.—*Revue de Laryngol., d' Otol. et de Rhinol.*, December 1, 1883.

VERATRINE IN TREMBLING.—M. BAZILE FÉRIS has used veratrine in some cases of trembling, and has obtained excellent results. He has used it in thirteen cases; six being of alcoholic origin, two came on after typhoid fever, and one was due to sclerosis *en plaques*. All patients were rapidly relieved of the disagreeable symptoms.

Féris ordinarily gives veratrine in pills containing gr. $\frac{1}{130}$ each, the dose being four pills, to be taken during the day. From his results he draws the following conclusions: Trembling dependent upon alcoholism, or upon affections of the nervous system, or consecutive to pyrexiæ, disappears under the veratrine treatment. The action of the drug is almost instantaneous, but the administration should be kept up for some time after the trembling has disappeared.—*Journ. de Méd. de Paris*, Dec. 8, 1883.

INJECTION OF TINCTURE OF IODINE INTO OVARIAN CYSTS.—CANTIERI has adopted this method in two cases, with good results.

Commencing at the superior part of the cyst, he inserted the needle of a Pravaz canula, and injected half a canulaful of tincture of iodine, this being repeated from four to eight times, at intervals, until the lower portion of the cyst was reached. In neither of the two cases was there collapse, intoxication, or inflammation, and there was only slight fever. The size of the tumor greatly diminished. In cases of multilocular cysts, the injections should be multiple.—*L' Imparziale*, Dec. 1883.

TEARS OF BLOOD.—This rare phenomenon, the reality of which has often been doubted, seems however, to occur under certain circumstances. Damalix has published an interesting paper on this subject in the *Archives d' Ophthalmologie*. He was led to study it by the observation of a case in M. Panas's wards. The patient, a young, hysterical girl, said that she had often noticed a flow of blood from her eyes, and spots of blood on her handkerchief after wiping them. For some time the hemorrhage occurred every night. A careful examination of the eyes showed nothing abnormal, but there were photophobia, facial neuralgia, and considerable blepharospasm. This case, as M. Damalix himself says, cannot be considered as conclusive, in spite of the probable veracity of the girl and her parents, as the hemorrhage was never seen by him. But there are on record some observations which do not leave room for doubt. In a case of Hauser, and in another of M. Brun, the observer could actually see the blood flowing from the eyes like tears; there was no possibility of trickery, and microscopical examination of the fluid showed that it was really blood. As for the diagnosis, the name blood-tears must not be applied to the various forms of hemorrhage caused by some organic lesion of the mucous membrane, such as small polypi, etc. The true form has nothing to do with any visible lesion, and the course of the accidents is remarkably irregular. Sometimes there are no premonitory signs, the blood appearing without effort or pain; in other cases, the patient feels for some time pain in the forehead, or at the root of the nose, or, it may be, a feeling of tickling and heat in the lids, which disappears when the blood begins to flow. The amount of blood lost varies from a few drops to a wineglassful; the flow never lasts more than

a few minutes, is always intermittent, and generally coincides with other hemorrhages in the skin or mucous membranes, or, on the contrary, with *suppressio mensium*. A study of the etiology of the disease shows that it is most frequent in hysterical women suffering from anæmia or hæmophilia.—*British Med. Journ.*, Dec. 8, 1883.

The Treatment of Leukæmia, Pseudo-leukæmia, and Progressive Pernicious Anæmia by Arsenic.—Dr. Warfvinge, of Stockholm, reports eleven cases of progressive pernicious anæmia, as many of pseudo-leukæmia, and two cases of leukæmia treated at the Sablatsberg Hospital. The two cases of leukæmia and seven of pseudo-leukæmia and progressive anæmia were put on arsenic treatment.

The first case of leukæmia was apparently completely cured after three months' treatment by arsenic; there had been a great deal of lymphatic enlargement, but the glands returned to their normal volume, and the blood-globules increased to the normal number. The second case of leukæmia was in a very advanced stage, the spleen being enormously enlarged, and there were an equal number of white and red corpuscles. After twelve weeks of arsenic treatment, the volume of the spleen was considerably diminished, and the ratio of the white to the red globules had fallen to 1 : 14; the general health being also much better. During the course of the treatment several hypodermatic injections of Fowler's solution were made.

As to the cases of pseudo-leukæmia, the treatment was without effect in two, but gave the best results in the other five cases. In one case, of lymphatic form, the cachexia and marasmus attained a marked degree in spite of the administration of the iodide of iron; but after five weeks of arsenic treatment, the amelioration was very marked. In another case, of lymphatic form, the arsenic evidently acted in reducing the size of the ganglia, but the patient died of asthma, caused probably by pressure of the enlarged ganglia of the mediastinum. Two other cases left the hospital with all the signs of health, and a fifth was very much better.

The cases of progressive pernicious anæmia were always ameliorated, and sometimes cured. Treatment by arsenic was only begun after a long and fruitless trial with iron and tonics. Amelioration was manifest after a short time, and the quantity of red blood-corpuscles was sensibly and rapidly increased. In some cases there was a relapse, followed by the death of the patient. —*Centralbl. f. gesammt. Therap.*, No. ix., 1883.

Extirpation of the Larynx and Thyroid Gland.—Dr. Novaro performed this operation at the Ospitale S. Giovanni, in Turin, on October 1st. The patient was a male, æt. 54 years. The operation was performed on account of epithelioma involving the larynx, thyroid body, and a part of the wall of the pharynx, the latter being also excised. The patient died of pneumonia a month after the operation.—*Gaz. degli Ospitali*, Dec. 9, 1883.

First Lung Resection in Italy.—Ruggi recently performed this operation on a woman æt. 30, who had phthisical cavities in the upper lobe of the right lung. She also had fungous arthritis of the knee-joint. The second and third ribs were resected, with their cartilages, for about two and four-fifths inches; the pleura was opened and separated from the lung, without any respiratory or circulatory troubles. The whole of the upper right lobe was removed by means of Billroth's pincers. The temperature and respiration became normal after six hours. The patient died on the ninth day of carbolic acid poisoning.

Mosler, in commenting upon this case, declares that while traumatism, bronchiectatic caverns, and gangrene may be legitimate excuses for this operation, tuberculosis is not.—*Centralbl. f. klin. Med.*, Dec. 1, 1883.

Scleroderma.—At the close of an article on scleroderma in the adult, Dr. Giorgio Nicolich draws the following conclusions:

Scleroderma is a special inflammation of the skin and subcutaneous connective tissue, which at times affects the mucous membrane of the mouth and vagina. Its course is very slow, the initial symptom being hyperplasia; the final, atrophy of the affected part. It is in all probability secondary to neurotrophic alterations.

The disease may affect the skin of the whole body, but more often that of the upper half. Females are more disposed to the disease, and it is principally observed between the ages of twenty and thirty years.

The most frequent cause is the action of cold on the sweating skin, or simply catching cold. Cure is possible only in the first stage of the disease, though notable amelioration can be obtained in the second stage. Massage and electricity give the best results.—*Lo Sperimentale*, October, 1883.

Turpentine-Iodoform.—De Renzi recommends a solution of iodoform in turpentine as an efficacious inhalant in pulmonary disorders, in phthisis especially. He has used this mixture for some time with very good results. Five or six drops of the solution are used every two hours, placed on a piece of wadding in an inhaler.—*L'Imparziale*, November, 1883.

Nephrectomy.—Dr. N. P. Dandridge, of Cincinnati, reports in *The Cincinnati Lancet and Clinic*, of December 29th, the case of an unmarried female, aged twenty-two, from whom, on November 2d, he extirpated the right kidney by the median incision on account of caseous pyelitis. The patient died the same day.

On June 19, 1883, at the Sussex County Hospital, Brighton, Mr. Jowers extirpated the left kidney, on account of scrofulous degeneration, in a married female aged fifty-five, who suffered from constant dull pain in the abdomen, associated with a hard, movable mass, about the size of a large cocoanut, and frequent attacks of hæmaturia. The operation was performed by the abdominal incision. The patient died on the 21st.

Amyotrophic Lateral Sclerosis.—At a late meeting of the Société de Biologie, M. Marie reported the results of an autopsy made on a woman, in the service of M. Charcot, who had been affected with this disease. The chief fact, of great physiological and clinical interest, consisted in the presence of profound alterations of the motor convolutions, granular bodies being found in the white substance, and the large pyramidal cells had disappeared. The granular bodies could be followed

into the direct and crossed pyramidal fascia of the cord, into the protuberance and peduncles, and into the internal capsule to the point indicated by Flechsig as giving passage to the fibres of the pyramidal fascia; and the fibres of the same fascia were found altered in the white substance of the frontal and ascending parietal convolutions.

These facts establish anatomically the continuity of the fibres of the pyramidal fascia from the cortex to the lateral regions of the cord, and support Charcot's views of the systemic nature of the disease.—*Gaz. Hebdomadaire*, January 4, 1884.

DYSPHAGIA FROM PARALYSIS OF THE LEFT RECURRENT LARYNGEAL.—K. DÉHIO reports the case of a woman, aged fifty-four years, who had had a hard chill two weeks before her admission into the hospital. At the time of her admission, she was somewhat feverish, respiration accelerated, and the end of the nose and the lips were cyanosed; the cough was paroxysmal, but did not commence by closure of the glottis; it was very harsh, and the voice was a monotone. On laryngoscopic examination, the glottis was seen to be drawn to the right, raised, and almost immovable, the right side only being slightly drawn down during the efforts at phonation and deglutition. The left ary-epiglottic ligament showed the characteristic signs of paralysis of the left recurrent laryngeal.

The clinical interest of the case, which was ameliorated by faradization and injections of strychnia, consisted in the association of paralysis of the recurrent with concomitant trouble of the act of deglutition. The cases reported by Gerhardt, Türck, and Von Ziemssen, caused by diphtheria, bulbar paralysis, and other affections of the cerebral centres, all point to local muscular paralysis, or to a simultaneous affection of the superior laryngeal, and in these cases the troubles of deglutition are explained by paralysis of the ary-epiglottic muscles. In the present case, to explain this trouble, the author admits that the left recurrent innervates the ary-epiglottic muscle of the opposite side.—*Revue Mens. de Laryngol. d'Otol.*, etc., January, 1884.

TUBERCULOUS NODULES IN LUPUS.—M. MALHERBE has recently made a histological examination of a tumor, diagnosticated as lupus, removed from the preauricular region of a woman æt. 34. Tuberculous nodules were found in it, furnishing a rare confirmation of the opinions of those who class lupus among the local tuberculoses.—*Gaz. Méd. de Nantes*, December 9, 1883.

SUDDEN DEATH IN DIABETES.—Of four hundred cases of diabetes observed by FRERICHS, a certain number died suddenly. The common termination was by coma, though its evolution varied in many cases. The coma generally came on after some prolonged effort, great feebleness, coma, and death rapidly resulting. In other cases the course was less rapid; after some premonitory symptoms, cephalalgia, delirium, pains, attacks of mania, and dyspnœa, with or without cyanosis, come on: the breath has a sweetish odor which resembles that of acetone or chloroform; recovery is rare. This form lasts from three to five days. In a third series of cases pain and dyspnœa are absent, coma gradually comes on, the odor of the breath becomes more pronounced, and the urine gives a reddish-purple reaction with perchloride of iron. Coma is more frequent than is generally supposed, and, with phthisis, constitutes the great danger for diabetics.

Frerichs thinks that in the first group the cause of death is cardiac paralysis, due to degeneration of the cardiac muscle. In the last two groups we can simply ascribe it to "diabetic intoxication" without being able to say what the poison is.—*Gaz. Hebdom.*, January 4, 1884.

PORRO OPERATION.—DR. VIOLANI performed this operation on December 18th. The patient died in a few days of septic peritonitis.—*Gaz. Med. di Torino.*

EXTRACT OF PHYSOSTIGMA IN DIARRHŒA.—MASCHKA has several times used the extract of the Calabar bean in diarrhœa, and with a good deal of success, finding it superior to opium. It is very efficacious in the treatment of nervous or emotional diarrhœa, and the diarrhœa caused by acute intestinal catarrh. There is but little danger in its administration; less than in the usual opiates, especially in children, and considerably less than with the extract of nux vomica, which has analogous properties.—*Revue Scientifique*, January 5, 1884.

CYSTOTOMY FOR STRUMOUS CYSTITIS.—At the meeting of the Liverpool Medical Institution on December 20, 1883, DR. RAWDON brought forward the case of a boy, aged seven, who had severe cystitis. He was a weakly boy; micturition was very frequent and painful, and the urine contained pus and blood. Notwithstanding general treatment, he was rapidly getting worse, when cystotomy was decided upon. Under chloroform, the usual lithotomy wound was made upon a staff; the bladder was explored without detecting anything, and a lithotomy tube introduced. Immediate relief was experienced. Appetite and sleep returned, and the boy was, after a time, allowed to go home with the wound partially closed. For two or three months he was able to run about, when the tubercular mischief in the kidney set up a lumbar abscess, which soon terminated fatally. The urinary organs affected with tuberculosis were shown.

MR. REGINALD HARRISON strongly recommended cystotomy, not only for cases of chronic cystitis from other causes, which might be cured by it, but for the relief it afforded to the distressing symptoms which accompanied cases like the present. He had now performed the operation a great many times, and was much impressed with the good results it yielded.—*Lancet*, January 5, 1884.

LIGATION OF THE COMMON CAROTID IN A CHILD.—M. BERTIN, of Cray, reports the case of a child, one year of age, in which the common carotid was successfully ligated for angioma of the parotid region of the jaw.—*Revue de Thérap.*, January 15, 1884.

FLOATING KIDNEY.—M. BERTIN, of Cray, describes a case of floating kidney which came into contact with the uterus. It could be felt by vaginal examination, and was easily displaced by movements and changes of position.—*Revue de Thérap.*, January 15, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 2, 1884.

GOUTY NEPHRITIS.

IN a very interesting paper upon this subject, read before the Berlin Medical Society, which appears in the *Berliner klinische Wochenschrift* for January 7th, VIRCHOW first calls attention to the fact that the association of gout with uric acid-gravel and stone, is, in his experience, a very much rarer event than is commonly supposed; that the number of cases of uric acid-stone or gravel of similar composition in the urinary passages, attributable to gout, is very few; while, on the other hand, gouty subjects are in small danger from such concretions. He calls attention, too, to the number of instances in which the morbid anatomy of gout is discoverable, consisting in the presence of numerous tophi of urate of sodium, often of considerable size, in the ears, on the hands and feet, and even in the foot and leg, without the paroxysms of pain which are considered almost essential to the diagnosis of this affection. These Virchow considers positive symptoms of gout, while the nodes and exostoses—true bony structures—which make up the morbid anatomy of *arthritis deformans*, and which have been more or less associated in the minds of physicians and others with gout, are no part of this affection, unless it happens, as once only occurred to him, that they are associated with the tophous deposits. He declares also that the theory which makes gout the result of the free consumption of albuminous food, is erroneous, because he has met it so frequently in the poorest classes, who are strangers to such a diet. He has, however, no hypotheses of his own to offer, but admits that the disposition is an hereditary one.

But, while gravel and larger concretions in the calyces are not a part of the pathology of gout, the presence of crystalline masses in the uriniferous tubules—not in the interstitial tissue, as Ebstein has announced—is a constant condition, and along with this, chronic interstitial nephritis. Usually, the precipitates are found in the middle section of the medullary cones, more seldom at the apex of the papillæ, and most rarely at their circumference. In these situations they are visible to the naked eye. Microscopically, the concretions are made up of rhombic columns perfectly colorless.

The interstitial nephritis, which is also a part of this condition, and which illustrates the typical chronic form, or contracted kidney, involves, not the medulla, but the cortex. And here the tubules are free from concretions. What, then, can be the cause of the inflammation? In this respect, the inflamed kidney is comparable to the inflamed joint, in which, too, the tophous deposit is not at the seat of inflammation, the synovial membrane, but in the cartilages and ligaments. It must, then, be the fluids charged with sodic urates—the urine in the one instance and the synovial fluid in the other—which are the irritant.

This being the case, can we not have a gouty nephritis which is not associated with urate deposits? This question Virchow answers by a very interesting account of his own case. He had never in his life had an attack of gout. He had occasionally had trifling swellings about his finger-joints, which were red and painful, but without other symptoms. In the previous year, however, his bladder became irritable. There was frequent desire to pass water, and a burning sensation in the urethra, especially at the external orifice. This was intermittent, and he gave it little attention. But the disappearance of a decided feverish state in November of that year was followed by a decided irritation of the urinary organs, with passage by the urethra of almost pure pus, oftentimes but a few drops at a time. Surgical examination failed to discover the seat of its origin. Albumen and casts were also present. He then set himself to determine the source of this pus. He reasoned, if it is a product of mucous membrane, then must it be mixed with an appreciable amount of mucus, which is not the case if it be pus from an abscess or ulcer. To determine this, he added strong acetic acid to the slide, and was astonished at the sudden appearance of a large number of crystals of uric acid, obscuring for the time all other objects. Reasoning from this fact, he concluded that a decided alkaline treatment should help him. He immediately took a large dose of borate of soda, followed by Karlsbad water in the morning, with immediate relief. He continued this treatment,

and in three months there was neither pus, albumen, nor casts, and his urine, in his own words, "ist so klar wie der einer Jungfrau."

That the irritation and inflammation here referred to were the result of the action of urine highly charged with acid urates there can be no doubt, but whether our English confréres, to whom we owe most of our knowledge of gout, will admit this to be a case of that disease we are not so sure. If, however, the pathology of gout consists in a surcharging of the blood and all the fluids of the body with uric acid compounds, we do not see any reason why it should not be so included; and Virchow's experience suggests a mode of examination which we are confident has been rarely applied, and which, if followed, may often lead to similar practical results.

THE RADICAL CURE OF ARTIFICIAL ANUS.

SEVERAL papers have appeared during the past year, which throw some light upon the comparative value and safety of Dupuytren's operation and the more recent procedure of resecting a portion of the bowel and uniting the divided ends with sutures, for the relief of artificial anus. In the operation of the French surgeon, it will be remembered, the object is to destroy the éperon or spur-like process with the enterotome, so as to reëstablish the natural route of the feces, and leave the closure of the abnormal opening to the efforts of nature, or promote its cicatrization by the hot iron or other measures, or, finally, fill the defect by a plastic operation.

Of 83 cases of this operation, collected by HEIMANN, in the *Deutsche medicinische Wochenschrift*, No. 7, 1883, 7, or 8.5 per cent., died, 50, or 60.2 per cent., were complete cures, and 26, or 31.3 per cent., were partially successful, that is to say, the subjects recovered with a small fistule, compelling them to wear a compress and a bandage to prevent the escape of the intestinal contents. The time required for the cure varied from two to six months. At least three of the deaths were due to causes unconnected with the procedure, so that it may be said to be comparatively free from danger.

In view of the uncertainty and tediousness of Dupuytren's operation, the elder Gross, thirty-seven years ago, suggested to a patient excision of a portion of the bowel with suturing of the cut ends, but the proposal was declined. Hence it remained for Dr. Kinloch, of Charleston, S. C., in 1863, to carry the suggestion into effect, the report of the case having been published in THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, vol. liv., 1867. Although the operation failed, to Dr. Kinloch belongs the credit of having been the first to practise enterectomy and enterorrhaphy for the lesion under consideration.

Up to the present date abdominal incision, with intestinal resection and suturing, has been practised in at least 37 instances, of which 29 have been analyzed in a valuable paper contributed to the *Révue de Chirurgie*, No. 7, 1883, by MM. BOUILLY and ASSAKY. The operators were Billroth in 7 cases, Schede in 3 cases, Julliard, Meusel, Rydygier, Schinzinger, and Wienlechner, each in 2 cases, and Albert, Bardenheuer, Baum, Bouilly, Dumreicher, Dittel, Esmarch, Gussenbauer, Hofmokl, Hueter, Kinloch, Madelung, Novaro, Schonborn, Tauber, Thiersch, and Weiss, respectively, in 1 case. Of the 37, 11, or 30 per cent., died, and 26, or 70 per cent., recovered.

The cause of death was peritonitis in 7, embolism of the pulmonary artery in 1, collapse in 1, pneumonia in 1, and ileus in 1. Of the recoveries 25 were complete cures, and 1 failed. All of the operations, with the exception of that of Kinloch, which recovered, were done under antiseptic precautions.

It will thus be seen that, when compared with the more simple operation, enterectomy is a serious procedure. Even if we deduct five deaths from peritonitis due to the escape of the contents of the intestine into the peritoneal cavity from the faulty application of the sutures, which were, as a rule, composed of catgut, perfect operations afford a mortality of 19.35 per cent., as against 5 per cent. for Dupuytren's method. Hence, we think that the procedure should be reserved, first, for the more simple cases in which compression, cauterization, the enterotome, and autoplasty have failed; secondly, for cases of great destruction of the intestinal wall, with extensive prolapse of the mucous membrane, and with or without invagination of the upper portion of the gut; and, thirdly, for the cases in which the ends of the intestine are so disposed that, even after the destruction of the éperon, there could be no reëstablishment of the natural course of the feces, as would happen if the lower end of the gut were placed above the upper end, if the two segments crossed each other at a right angle, or if there were a notable difference in the calibre of the two ends of the intestine.

THE HOT WATER MANIA.

THE hot water drinking mania, is one of those periodical sanitary epidemics, which, like certain moral epidemics, now and then rage through this country. The secular newspapers have taken it up, and elaborate editorials indicate the interest which the general public has manifested in this supposed new remedy. The persistence of the mania is a proof of the vitality of the system. The epidemic had long since spent its force, if its energy had not been recruited from the aggressive enthusiasm of new converts and disciples.

At the risk of chilling the spirits of hot water disciples and advocates, we are compelled to maintain that the method is not new. It is always an ungracious task to temper enthusiasm and to substitute a sober realism for the free flights of the ardent imagination, but we are restrained by our duty as medical journalists, to the domain of scientific verity. The use of hot water as a beverage, had its real origin in the method of stomach irrigation inaugurated several years ago by our German colleagues, as a remedy for chronic gastric catarrh. An ingenious and pseudo-scientific New York empiric, bethought himself of hot water drinking as a substitute for hot water irrigation. But Dr. Sangrado had preceded the modern empiric in the hot water practice. In the claim for priority of discovery, we hold that the patron of *Gil Blas*, is entitled to the honors, for did not the system of Sangrado consist in bleeding *ad deliquum animi*, and copious libations of warm water? This interesting historical question settled, we can now proceed to determine the real value of the practice.

> ——"All the water in the ocean
> Can never turn a swan's black legs to white,"

is a saying of Shakespeare; so no amount of mere assertion can prove the value of hot water as a remedy. Sangrado was besought by his pupil Gil Blas to give up a practice which had proved so deadly, but this great medical philosopher, like so many of his ilk in our day retorted "have I not written a book?" which, as it was devoted to proving the value of the system, must not be disgraced by a change of opinion on the part of its author. Surely it is "the irony of fate," to have hot water revived as a remedy, by modern science.

Hot water serves several purposes: it is a means of applying heat to the interior of the body, for a well-instructed patient may drink water at 120° F. The effect of the heat is to dilate the stomach vessels, and thus increase the blood-supply to the gastric glands. An increase of functional activity is thereby induced. The reflex effect of the increased heat is manifest in a considerable stimulation of the solar plexus, the organs of vegetative life, and the circulatory system. The result of such stimulation must necessarily be a widespread increase of functional activity.

Large draughts of hot water act mechanically by dislodging the mucus adherent to the mucous membrane, by dissolving the alimentary refuse, and by washing into the circulation soluble constituents not disposed of in the ordinary process of digestion. The result of this is to increase the primary assimilation in an effective way. To a less extent, draughts of hot water, therefore, wash out the stomach, and prepare the organ for better work, as irrigation does.

The picture has its sombre side. Water drinking, though the water be hot, is not without its drawbacks. There are those who believe that too much water is an impossibility. The late Dr. John F. Meigs was one of those—an apostle of water-drinking—and he has had many followers. Even so good a thing as water may be abused. Too much water taken during the progress of digestion, may so far dilute the gastric juice as to render it unequal to its proper work. The digestive process being thus weakened, a condition of anæmia results. For the purposes indicated above, hot water should be taken either before digestion has begun, or after it is completed. In the use of this agent, as of all other therapeutical remedies, the true principle is to adapt the remedy to the conditions present. Hence, it follows that each case must be studied by and of itself, and hot water given or withheld, according to the state of the stomach, or of the general system.

HOSPITAL TRAINED NURSES.

From all sides comes testimony in favor of this comparatively recent system of training nurses. Few physicians in active practice have failed to share its advantages. In place of the ignorant, garrulous, obtrusive, yet inefficient, and often filthy crone of fifteen years ago, we meet in the sick-room the quiet, intelligent, refined, and helpful woman, whose presence is a pleasure and comfort to the physician as well as to his patient.

It is evident, too, that this new field of operation for women has increased the opportunities of the better class for earning a living under circumstances which are not lowering to self-respect or dignity, or inconsistent with that refinement and intelligence which are woman's most effective adornments. The companion of ladies, it is necessary that she herself should have ladylike attributes, and the feeling that the possession of these, and the qualifications that make her an efficient nurse, are necessary to success, tend to increase both. At the same time training does not exclude from the ranks girls of humbler origin and more limited advantages, who are nevertheless teachable and susceptible of refinement.

Another advantage of the system of training schools for nurses accrues to the patients in the hospitals, in connection with which the schools are established. To these the training school is a great boon. The old-time hospital nurse was worse than the private nurse of the same period; for the patient of the latter was, as a rule, at least protected from

cruelty and generally from positive neglect. A catalogue of the discomforts, and even injuries sustained by hospital patients, due to the neglect and cruelty of their attendants would be heartrending. Especially is this the case where pauper or convict help is employed for this purpose. We are quite sure that the supply would not exceed the demand if every general hospital of any size had connected with it a training school whose pupils should take the place of the illy, but still sufficiently, paid—when their qualifications are considered—nurses of to-day.

It has been suggested that similar schools should be established for males. But we doubt whether they would be successful. Woman possesses naturally many of the qualifications for nursing, and the teaching and example of years cannot give them to men. On the other hand, men of the required intelligence are not likely to be found ready to submit to the regulations and to take the time necessary to secure the proper training.

In this connection, we may be permitted to say a word in relation to nurse directories, of which the two most notable examples exist in Boston and Philadelphia. The advantages of these can only be appreciated by those who have gone through the experience of getting a nurse under the old and new systems, an hour or two sufficing to obtain a competent nurse by the latter, when by the former a laborious search, extending through an entire day, often resulted in securing an unsatisfactory substitute.

The Boston Directory is an admirable success, resulting last year, we are informed, in a profit of $1200, which was turned over to the Boston Medical Library Association. But from what we can learn, while the Philadelphia Directory is a success in most respects, the financial exhibit is not so satisfactory. We fear this is largely due to the fact that some of the most prominent physicians in Philadelphia are in the habit of sending their patients, to whom the trifling expense would be no consideration, not to the Directory, but to the house where the nurse they desire to employ happens then to be engaged. The nurse directory in every city is so great a convenience to physicians, patients, and nurses that it should have the benefit of their entire and unconditional support.

GOVERNMENT PATRONAGE OF MEDICAL INSTITUTIONS.

THOSE restless utilitarians who seek in State supervision of medical affairs the ultimate good, will be enlightened as to the tendency of such interference by watching some proposed legislation in the present Congress. One scheme is to establish a great medical university to teach all the methods of the so-called "schools." The most recent proposition is to compel the Army Medical Examining Board to accept the creeds of all comers, and to make no distinction between physicians and charlatans. The next step will be to constitute a board of Homœopathic examining surgeons to do justice to their system, for, with what grace can the present boards, composed of "old-school" surgeons, decide on the merits of "new-school" candidates? The innovation at the University of Michigan, which gave a department to homœopathic practice, does not satisfy the Eclectics, and they demand, and doubtless will soon receive, some kind of recognition of their "claims."

Those gentlemen of the profession who wish a State Board of Examiners, who alone shall have power to grant licenses, like the *Staats-Examen* of Germany, should make up their minds to a mixed commission of a political complexion, varying with the changing fortunes of political parties. It will be a sad day for our medical institutions when places in them shall be the prey of political rivalry. It is wiser to reform ourselves—to improve our methods by our own machinery, and to increase our attainments by the natural evolution of our own powers.

OUR attention has recently been called to a form of medical advertising, which has grown out of the introduction of the telephone into general use. The telephone exchanges supply their patrons with printed lists of their subscribers, and some of the more enterprising of them have their lists arranged according to trades, as well as alphabetically, and then, with a view of bringing more grist to their mill, they have added an advertising sheet for those of their patrons who desire, for a consideration, to bring their wares more prominently to the attention of the public.

We have recently seen the pamphlet list of a Western exchange, the last page of the cover of which is entirely devoted to the cards of a few of the more "enterprising" doctors of the town, who thus conspicuously advertise their address and telephone number. An examination of this list shows it to be made up of a motley crew. We find the names of 2 magnetics, 1 eclectic, 17 regulars, 5 homœopaths, and 1 botanic, intermingled, and without any mark by which the public can distinguish the peculiar methods of practice of each.

This is a new outcropping of the trade spirit, and we are glad to learn that the Polk County (Iowa) Medical Society has formally resolved that this method of advertising "is not conducive to the best interests of the profession"—indeed they might have said it is injurious to the profession's best interests. It is contrary to the spirit of the Code of

Ethics, and directly lowers the profession to a trade level.

We trust that wherever this new form of advertising has grown up, the profession will promptly condemn it in unmistakable language.

REVIEWS.

The Diagnosis and Treatment of the Diseases of the Ear. By Oren D. Pomeroy, M.D., Surgeon to the Manhattan Eye and Ear Hospital, etc. 8vo. pp. 392. New York: Bermingham & Co., 1883.

This book belongs to that class of works on ear disease which appears to be growing fashionable, viz., one in which the authors, for there are already several in the field, seem to think that anatomy and physiology can be dispensed with. This is all the more surprising and deplorable because the books are addressed not to specialists, who may fairly be presumed to know the minute anatomy and physiology of the ear, but to the general practitioner and the student, who presumably are not very familiar with this abstruse subject. Hence these books, at best, constitute what may be termed second volumes of a work in which the first volumes, which should be on anatomy and physiology, are wanting.

They are too anticipatory in arrangement, and partake of the unfortunate nature of the method of medical instruction which hurries the medical student from his anatomy and elementary branches to the clinic-room and the hospital, to learn to treat pneumonia and hip-joint disease, before he knows the structure of the lung or the anatomy of the acetabulum.

This book contains many pleasant allusions to the work of the author's colleagues in this specialty, and ample justice having been done in this respect, the author has brought his book "down to date" in its encyclopædic information upon treatment. Many valuable and important facts have been brought out, as a reference to Holt's method of inflation of the tympana, by puffing out the cheeks instead of swallowing water at the moment of inflation; it seems superior to Politzer's method in our hands. It is with pleasure we note also that the connection, at least clinically, between progressive locomotor ataxia and deafness has been laid before the reader. It is to be regretted that there has been some very careless proof-reading, but it is to be hoped that the errors will soon be corrigible in a new edition of the work. We refer to such mistakes in spelling as "Brunston" for Brunton, "Bertholet" for Bertolet, "Séiglè" for Siegle, "Botticher" for Boetcher, "Lascource" for Lasource, "Greene" for Green, "Rholand" for Roland, "Wein" for Wien, among proper names, while among ordinary words, "acousticus" often appears for acusticus, even in the table of contents, and douche appears as "douché." On pp. 39 and 40 there occurs the following quotation from Politzer's *Lehrbuch:* "The inclination of the drum-membrane in children has hitherto been described as nearly horizontal. By means of numerous measurements Dr. J. Pollak has shown this view to be erroneous, there being no perceptible difference in the inclination of this membrane in infancy and adult life." To this statement exception must be taken. If anyone will examine a preparation of the skull of an infant in which the membrana tympani is retained *in situ*, he will observe that the membrane conforms to the curve of the base of the skull, and is more nearly horizontal than otherwise, and much more so than in the adult or large child's skull. This fact has so much clinical importance, both in examinations and in operations on the membrane, in aiding us to decide the extent or absence of abnormal retraction, and the point in the membrane at which to make a proper incision, that it is necessary to question the accuracy of Pollak's observation.

We regret to find that many of the figures in the book, intended to represent normal and pathological conditions of the membrana tympani, as Figs. 17, 46, 68, 69, and 70, are extremely bad, but it is with pleasure we note the goodness of such figures as Nos. 20, 21, and 22, illustrative of perichondritis auriculæ.

The binding and the paper of the book are handsome, but the print is a little too fine and too close to be easy for reading, though, of course, it makes the book compact, and aids the author to make the information contained in its numerous pages, very copious. The work, as a whole, is certainly a valuable addition to the literature pertaining to the diagnosis and treatment of diseases of the ear.

Transactions of the Pathological Society of Philadelphia. Volume Tenth. 8vo. pp. xxii. 307. Philadelphia: 1882.

The tenth volume of the *Transactions of the Pathological Society of Philadelphia* contains, like most other volumes of the same character, a great deal that is interesting intermingled with much that is merely sketchy, or without interest apart from the specimens described. The arrangement of the matter in the volume before us is admirable, the specimens and their descriptions, or the papers accompanying their presentation being carefully classified according to location. In this respect the *Transactions* would serve as an admirable catalogue of the specimens in the museum of the Society.

Volumes I. to IX. of this series, we are informed, can be purchased for fifty cents a volume, upon application to the Treasurer, No. 1423 Walnut Street, Philadelphia.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 8, 1884.

The President, Robert F. Weir, M.D., in the Chair.

MULTIPLE INCISIONS FOR CICATRICIAL CONTRACTION.

Dr. A. C. Post presented a boy who had received an injury of the palmar surface of the ring finger of the left hand, and as a result the finger was bent at an angle of about seventy or eighty degrees. He operated for the deformity by making a series of transverse incisions, probably ten or twelve in number, and subsequently dressing the wounds with subnitrate of bismuth, and applying a metallic splint. The case illustrated the benefit of multiple instead of single incisions.

COMPOUND FRACTURE OF THE HUMERUS, INVOLVING THE SHOULDER-JOINT.

DR. L. A. STIMSON presented a patient, a man thirty-five years of age, who fell two stories, striking his arm while on the way down upon a railing, and producing a compound fracture of the upper end of the humerus, communicating largely with the shoulder-joint, the wound extending from the coracoid process across the upper part of the arm. The wound was washed with a bichloride solution, one to two thousand, partly closed by sutures, two drainage-tubes were inserted, and antiseptic gauze applied. The interest in the case was confined to the plaster dressing which was used. It was a combination of plaster dressing upon the arm and a plaster jacket upon the body, united by three iron cross-pieces, which held them so firmly that the patient could be moved or turned in any direction without producing pain. Rapid recovery took place with a movable joint.

SPONTANEOUS DISLOCATION OF THE HIP-JOINT, OCCURRING IN THE COURSE OF ACUTE ARTICULAR RHEUMATISM.

DR. STIMSON also presented a patient, a woman thirty-seven years of age, who had an attack of rheumatism in December, 1882. The history of the attack was obscure, but the patient said that many joints were involved, that she remained ill for a long time, and that the deformity occurred as early, at least, as the following April. She finally came to Bellevue Hospital last summer, where Dr. Stimson saw her first in the month of September, and recognized a dislocation of the right hip-joint, backwards, upon the ilium. The interest of the case was partly in the rarity of the occurrence, and also the facility with which the lesion may be overlooked. The subject has been recently written upon by French surgeons, and he had nothing to add except to say that the symptom of sudden cessation of pain sometimes noted at the moment the dislocation occurs, does not appear to have been present in this case.

EXSECTION OF THE WRIST-JOINT.

DR. A. G. GERSTER presented a patient upon whom he performed exsection of the wrist-joint November 5, 1883. The patient, a woman thirty years old, had had a severe attack of acute articular rheumatism, which involved nearly every joint of the body, all of which regained their functional ability except the wrist-joint, which remained swollen, hot, and stiff. The patient was treated in the medical wards by the use of internal remedies, counter-irritation and local applications, but without much improvement, and finally she was transferred to the surgical side, where Dr. Gerster found very extensive agglutination of the flexor and extensor tendons in their sheaths, and the hand resembled more a flipper than a hand. With reference to the joint proper, he found evidence of disease of the radio-carpal articulation. The condition of the carpus proper, however, made him anticipate that the carpal joint proper was not involved. On the inner side, moreover, at a point corresponding to the radial artery, a reddened spot appeared on the skin, showing that perforation was imminent. He proposed to the patient to have the joint examined, but if the condition were such as demanded it, finally to perform exsection. She consented to the operation, and Dr. Gerster made a lateral incision upon the ulnar side, wishing first to remove the ulna and thereby increase the facility with which the radius could be removed. In other words, he performed Lister's operation. Having exsected the carpal ends of the radius and ulna, the wound was closed and capillary drainage established by the introduction of a few strands of catgut. A bichloride solution was applied, and sufficient support was given by antiseptic dressings to obviate the necessity of using a splint. No fever whatever followed the operation, and on the tenth day, when the dressing was changed, it was found that primary union of the wound had taken place. The small strips of iodoform gauze placed immediately over the wound were simply colored with blood, but the remainder of the dressing was perfectly clean. Active and passive motion was begun on the second day after removal of the dressings, and had been continued. The flail-like mobility was considerable after the operation, but this has been improved, and the patient is now able to extend and flex the hand without support, and the mobility of the fingers has also improved very much in consequence of careful orthopædic treatment.

Dr. Gerster expected that she would have a tolerably useful hand. The carpal ends of the radius and ulna to a distance of two inches were removed, and the rest of the carpus was allowed to remain. The ends of the radius and ulna which were removed were devoid of cartilage, and the joint contained a small quantity of sero-cheesy pus. The capsule of the joint was infiltrated and thickened, the inner aspect of it was red, giving the peculiar velvety appearance seen in joint disease, and the perforation mentioned as being imminent on the volar side of the joint was found to be due to the burrowing of pus. No examination was made for the tubercle bacillus.

DR. POST thought it a very unusual occurrence for such extensive disease of the joint to occur without involving the carpus.

REMOVAL OF THE SUPERIOR MAXILLARY DIVISION OF THE FIFTH NERVE AND MECKEL'S GANGLION BY CARNOCHAN'S OPERATION.

DR. J. W. HOWE presented a patient with the following history: The patient's name is Freidman, æt. 45, and a native of Hungary. Twelve years ago, without any appreciable cause, she felt a pain in the region of the lower bicuspid tooth on the right side. The pain gradually increased in frequency and in intensity. It was usually aggravated by exposure to cold and heat. The paroxysms continued up to within three years of her admission to the hospital, varying little in severity. The inferior maxillary was first involved. Three years ago pain appeared in the upper division of the fifth. It started on the slightest provocation. Mastication became so painful that nothing but liquid food could be taken. Laughing, sneezing, swallowing, crying, all occasioned exquisite pain. For a year previous to the operation the pain was almost continuous, and there were occasional exacerbations of such severity as to produce delirium. Nourishment could only be taken in small quantities, and as a consequence she became emaciated and weak. Dr. Henry Schweig, under whose care she is at this time, informs me that he administered morphine hypodermically, and endermically, by the mouth, with and without atropia, without any alleviation

of the pain. He could not administer more than fifteen minims without aggravating the mental trouble, so that it was impossible to give heroic doses of the drug. He also tried aconitia, without any effect. At my request he also tried hypodermics of strychnia and hypodermics of atropine, without avail. The galvanic current was also tried for four weeks, with no effect. The only drug from which an appreciable effect could be obtained was nitroglycerine. This medicine relieved the pain for two or three weeks and then failed like the other remedies. The Doctor then brought her to St. Francis Hospital, and I performed Carnochan's operation on May 29, 1883, removing the superior maxillary division of the fifth and Meckel's ganglion. For three days after the operation the patient slept well, and there was little or no pain excepting that which naturally results from the operation. At the end of that time she had severe pain in the region of the inferior dental, and a spasm of the muscles of the affected side. This disappeared and was replaced by a dull pain in the wound and in the ear. A drainage-tube was inserted, and through this a solution of chloral, ten grains to the ounce, was injected twice each day. This relieved the pain. She left the hospital on June 11th, almost entirely free from pain, and able to eat and sleep and live comfortably. It is now seven months since the operation, she has gained in weight and strength, and is free from pain unless exposed to very sudden changes of temperature. She eats and drinks with comfort, and considers herself greatly improved by the operation. Notwithstanding the good result, I am not in favor of the operation, as I think further experiments with medicine could gain the same result that I attained; more especially by resorting to the hypodermic injection of strychnia.

DOUBLE GENU-VALGUM OSTEOTOMY BY MCEWEN'S METHOD.

DR. W. T. BULL presented a patient with the following history:

J. H. H., æt. 16, errand boy; admitted August 15, 1883. For the past two years, patient states, both of his knees have been growing weaker; knocking against each other while he was walking or standing. This condition has grown much worse during the past four months. Family history good. General health always good.

When patient stands with his knees in apposition, and with his feet as closely approximated as possible, the distance between the internal malleoli equals eight and a quarter inches. When patient lies on his back, this distance equals nine and a quarter inches. Knee-joints are perfectly normal; internal condyle elongated.

Aug. 24.—At 2.30 P.M. patient etherized, Drs. Bull and Little operating. Incision was made on inner side of the right thigh, through the skin and underlying tissues down to the bone, according to McEwen's method. Bone was then partly divided by chiselling, the remainder of the bone being fractured by manual force. The small hemorrhage was controlled by pressure. The limb being forcibly straightened, the following dressing was applied: Small peat-bag was placed over wound, and a full Lister dressing applied from the ankle to the gluteal fold; over this was placed a loose plaster-of-Paris splint.

During operation, a stream of a solution of salicylic acid was constantly projected over wound. Before applying the dressing, wound was cleansed with a solution of hydrargyri bichloridum (one to one thousand). Same operation was then performed on the left leg, and a similar dressing applied.

7 P.M.—Patient made good recovery from ether; complains of considerable pain in left foot. Pain increased, and became so severe by 12 M. that splint was cut open and limb held in position by properly adjusted sand-bags.

℞.—Magendie, ♏v. By hypodermic.

Aug. 25.—Pain continues. In both feet there is a sensation of numbness, and well-marked signs of retarded circulation. Morning, temperature 99.2°, pulse 96. At 12 M. both dressings were removed, and fresh Lister dressings were immediately applied. Long side-splints, reaching from axilla to the ankle were applied. Circulation began to improve, and in a few hours was apparently normal. Temperature 100.8°, pulse 105. General condition of patient very good.

26th.—During the following seven days patient had a slight recurring rise of temperature, with a pulse varying from 90 to 104. Temperature normal on ninth day, and continued so during the remainder of the treatment.

On Sept. 11 dressings removed. Wounds of original incisions nearly healed. Simple dressing was applied, with long side splints.

14th.—Plaster-of-Paris splint applied from toes to the groin of each leg.

On October 23d splints were removed. Right leg was found to be in excellent position; there was some slight tendency to a bending inwards of the left knee. Rubber bandages were then placed around each knee-joint, and patient allowed to walk about.

Dec. 15.—The bowing inwards of the left knee is almost entirely rectified by a brace, which extends from the sole of the foot to the upper portion of thigh, with a hinge-joint at the knee.

SUB-TROCHANTERIC OSTEOTOMY OF THE NECK OF THE FEMUR FOR CONTRACTURE AND ANCHYLOSIS OF THE HIP.

DR. W. T. BULL presented a patient showing the result of the above operation. Mary C., ten years of age, born in the United States, was admitted to St. Luke's Hospital, September 14, 1883. She was healthy until three and a half years old; then without any injury she commenced to develop hip-joint disease of left limb. Treated for five years at Hospital for Ruptured and Crippled. Patient left that hospital when eight and a half years old, with limb in good position. Very soon afterwards contracture of hip-joint set in, and increased rapidly during the past six months. On admission, left thigh is flexed and adducted, so that patella is situated two and a quarter inches above opposite patella and outside the median line of right thigh. When patient lies with back on a table, thigh is ankylosed, so as to form nearly a right angle with longitudinal axis of body. Except for a very slight flexion of femur, movements at hip are wanting without ether. Under ether small amount of motion is possible when standing erect, toes of left foot are about five inches from ground, and heel fully a foot In walking patient places the toes of left limb only to the

floor, and locomotion is performed in a hopping style. Pelvis is very markedly tilted downwards on left side, and the lateral curvature of the spine is extreme. Motion in knee-joint is perfectly normal.

Head of trochanter on left side is one and a half inches above Nélaton's line. Muscular atrophy of left thigh shows a dimunition in size of two inches.

October 4.—Tenotomy performed on gracilis and adductor tendons. Open division of fascia and tendons below sup. spinous process of ilium; femur divided just below trochanter margin and wedge removed, the base of wedge measuring a half inch. Lister dressing with long side-splint applied. Extension applied.

October 26.—Wound of femur entirely healed. Other wounds nearly closed.

November 9.—Union of femur solid. Left leg shortened two and a quarter inches.

TRAUMATIC ANEURISM OF THE VERTEBRAL ARTERY.

THE PRESIDENT presented a patient who had had the above affection, and remarked that there were only ten cases upon record. Of thirty-two cases of wound of the artery collected by Fischer, nine eventuated in aneurism. For the injuries to this vessel, the carotid was tied twelve times, with an unfavorable result. In the aneurismal cases, the carotid artery was tied five times, the patients all dying. Once it was exposed, but not tied, and that patient recovered; but why is not clearly seen. In two cases the aneurism was cured by cutting down, opening the sac, and plugging the opening in the artery. In the patient presented this evening, the aneurism was cured by digital compression. The man was twenty-eight years of age, and on the eighth of December was struck with a knife, half an inch below the lobe of the right ear, just behind the jaw, his opponent standing in front of him and holding the weapon in his left hand. Considerable hemorrhage took place, though when the man entered the hospital he was not very much exsanguinated; and the bleeding having ceased, an iodoform pad was simply placed over the wound, which was not disturbed until the tenth day, when the dressings were removed, and the wound found healed. Forty-eight hours after the receipt of the wound, the patient experienced a peculiar sensation in the head, and sudden paralysis developed, involving the opposite arm, from which he has not yet entirely recovered; although there has, in this respect, recently been marked improvement. After removal of the dressings, a slight swelling at the posterior margin of the sterno-cleido-mastoid muscle, and just below the mastoid process, was observed. This tumor had a feeble pulsation, which gradually increased up to the beginning of last week, when the signs of an aneurism were strongly marked over a space two inches in diameter, and a bruit was heard. The diagnosis was made positive by pressure on the cardiac artery. When this was made upon a level with the thyroid cartilage, pulsations in the swelling were not arrested; but when pressure was made on a level with the tubercle of the sixth cervical vertebra pulsation in the tumor at once ceased; and when the pressure was removed, it immediately returned in full force again. The diagnosis was in this way made clear, and was corroborated by his colleague, Dr. Markoe. The question was, what should be done? The best suggestions which he had seen upon this subject were those by Holmes, in his article on aneurism, written in 1873. Dr. Weir finally determined, before opening the sac and plugging it (which had afforded the best outcome of treatment), first to apply ice, and, if that failed, to resort to digital compression; because he had found that pressure upwards and forwards upon the lower portion of the tumor arrested pulsation. He, therefore, secured a relay of medical students as assistants, and last Thursday—after having used ice for some days without any change in the tumor—he began, at twelve o'clock, the treatment by digital compression. At two o'clock the pulsations were almost arrested, and at three o'clock they had entirely ceased; but the pressure was kept up lightly until seven o'clock. Since that time there had been no trouble in this region, and the tumor has rapidly subsided. No cerebral trouble ensued during the treatment.

DR. L. A. STIMSON said he could add one case to the list of unsuccessful ligatures of the common carotid artery for wounds of the vertebral artery. The patient was in Bellevue Hospital. He had been wounded by a pistol ball, which entered the mouth, passed into the left side of the pharynx, and made its exit at the back of the neck. There had been a profuse hemorrhage, but when he saw the case bleeding had ceased. The hemorrhage recurred the next day, and the common carotid was tied by the house surgeon. The patient died within a few hours afterwards. At the autopsy, it was found that the ball had passed between the atlas and the skull, and had divided the vertebral artery.

DR. W. S. HALSTED referred to a case which he saw at the Chambers Street Hospital. It was one in which the patient had received a stab with a knife between the atlas and the occiput, producing paralysis on the opposite side and of the muscles supplied by the spinal accessory nerve upon the same side, and the vertebral artery was not injured.

REMOVAL OF LARGE URETHRAL CALCULI BY INCISION THROUGH THE PERINEUM; WEIGHT OF CALCULI, FOUR HUNDRED AND FOURTEEN GRAINS.

DR. JOSEPH W. HOWE presented specimens with the following history: An Italian, Stephen Canziani, æt. 31, was admitted to the surgical division of St. Francis Hospital on December 31, 1883, with the following history: At the age of thirteen he was troubled with stone in the bladder, which was removed by an Italian surgeon through an incision in the perineum. The wound in the perineum only partially healed, and a fistula remained, through which the urine escaped for several months. Some time afterwards the patient passed a small calculus through this opening. The exact time of this occurrence the patient does not remember. Shortly after the expulsion of this stone, the opening in the perineum closed, and he had no further trouble up to within five years of the date of entrance to the hospital. He then noticed a hard mass in the perineum, which gave him some pain on pressure, as well as pain on micturition. The mass grew slowly, with an increase in the pain. It was easily moved from side to side. A friend advised him to poultice the swelling in the perineum. After following this advice for a few weeks, the integument ulcerated, and a calculus the size of a pigeon's egg was extruded. The patient likened this mass to a piece

of hard rubber. From the passage of this stone the patient experienced great relief, and he had no special trouble for four years, when he noticed two protuberances in the perineum, which gave him pain on pressure as well as pain on micturition. The pain during the passage of the urine was of a burning character, and lasted some time after the urine was voided. There was also considerable difficulty in emptying the bladder. These prominences continued to increase until the patient's admission to St. Francis Hospital.

On examination I found two prominent enlargements occupying the median line of the perineum. They were both easily moved, or rather the tube in which they were contained readily moved from side to side. The upper tumor was about half an inch from the lower and larger one below. I could, however, draw them together, and by the rough grating make out their character. The upper end of the first calculus was situated about three inches and a half from the meatus, the second and larger one extended down to within half an inch of the anus. The patient did not seem to suffer much pain when they were handled.

On Saturday last, the 5th, the patient was etherized, the meatus, which was very narrow, was incised so as to admit a No. 18 American sound. Its passage down the urethra was unobstructed until the first calculus was reached. A No. 5 was then introduced, but failed to pass the obstruction. An incision was then made in the median line of the perineum, commencing at the middle of the upper calculus, at the upper boundary of the perineum, and extended down to within three-quarters of an inch of the anus. The upper stone was then pushed into the opening and extruded; the lower one was then removed by completing the incision through the perineal tissues. A further examination showed that the urethra was very much dilated from the lower caculus to the bladder.

I first passed one finger in through the neck and discovered another calculus inside the bladder. I introduced a second finger along with the first one, stretching the parts easily. A stone-forceps was then introduced, and the cystic calculus removed. The calculus which occupied the anterior portion of the urethra was found to weigh one hundred and thirty-five grains (Troy). It measured an inch and a half in length and three-quarters of an inch in its broadest diameter. The lower calculus weighs two hundred and seventy-nine grains, and is an inch and three-quarters in length and an inch and a half in its broadest diameter. The calculus taken from the bladder weighs three hundred and ninety-five grains, is two inches in length and an inch and an eighth in its transverse diameter. The patient's temperature last night was 99.5°, and he is so far doing well.

DR. A. C. POST said there was a case on record in which a stone passed spontaneously from the female urethra, and described to be as large as a goose egg. He thought a number of cases of this kind had occurred in both sexes, in which stones of very considerable size had passed through the dilated urethra. He was not able to give the particulars of a number of cases occurring in the practice of his son in Beyrout, but his impression was that in some of them the calculi were larger than that presented by Dr. Howe.

The Society then proceeded to the transaction of miscellaneous business.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 8, 1884.

THE PRESIDENT, WILLIAM J. MORTON, M.D., IN THE CHAIR.

DR. RALPH L. PARSONS read a paper on

DETENTION IN ASYLUMS.

He spoke first of the question, whether sane persons were not often improperly or unjustly detained in asylums for the insane; and secondly, whether many uncured and incurable patients who were now methodically detained in asylums might not advantageously be returned to their relatives, or placed in the care of private families under State supervision.

It was assumed, in the first instance, that the detention of patients after recovery had taken place, for a longer time than might be required, was quite possible, and even probable, in some instances. But he claimed that such detentions were not usually of serious import to the patient; that, on the other hand, too early discharge might be more injurious. It was also admitted that maliciously unjustifiable detentions were quite possible, as any other sort of injustice is possible on the part of persons holding positions of power and responsibility. But reasons were urged by Dr. Parsons in support of the belief that such malicious detentions were at least very rare; that sentiments of honor and professional pride were strong deterrents, to say nothing of the great danger of detection in the commission of the wrong, and the ease with which patients who were decidedly insane obtained their enlogement through the intervention of the courts.

Cogent reasons were given why various classes of convalescents ought to remain under asylum care for a period of time after they appeared to be well; as, for instance, when they would be immediately subjected to the exciting cause of their insanity on their return; when the progress toward convalescence had been characterized by relapses, or when dangerous delusions had been entertained and had faded away so gradually that there were difficulties in judging whether they had passed away entirely.

But, on the other hand, the discharge of certain uncured curables before they were well was advised, as when, after making a certain degree of improvement, this improvement stopped, and the patient seemed to retrograde. It might be safe and highly advisable to discharge some of these patients before they were well.

The major part of the paper was devoted, however, to an advocacy of the discharge from the asylum of harmless incurables and their return to the care of their friends, or placing them with ordinary families as boarders and in some sort as members of the families. It was claimed by the reader that, however comfortable and happy such patients may appear to be in large asylums, there are many causes of annoyance and discomfort that would not be experienced in ordinary family life; that notwithstanding the fine buildings they occupy, and their freedom from care, they are still prisoners and exposed to many disagreeable associations and associates.

Quotations were made from Dr. Bucknill and from Dr. Maudsley, strongly supporting these views.

The question was then considered, what classes of incurables might safely and with benefit be released from asylum restraints? since, in the case of a great majority of such patients moderate cost of maintenance would be essential, those only would be adopted who were quiet and orderly and would require no especial attendance or supervision. Habits of industry would be favorable.

Whether such patients would do better with their relatives or with strangers would depend on the circumstances of the family, the state of health, the surroundings, the feelings or notions of the patients, etc. It would be found, however, that many patients who would not do well with their own kindred would be happy, contented, and useful with congenial strangers. It would be impossible for the patient to resume his former position and influence in his own family, and hence he would be subjected to irritating restrictions and annoyances there.

As a preliminary measure, a system of legalized furloughs was advocated, to the end that at first the patient might still be under legal restrictions, and easily returned to the asylum if the trial at large should prove a failure.

Properly constituted authorities should make the selection of patients for the trial, with the assistance and under the advice of the asylum superintendent. The families in which the patients should be placed should be selected with great care. While at first there might be found very few suitable families who would assume the charge, it was thought that, when a beginning had been made, plenty of suitable homes would be offered. Reference was made to the multitude of respectable and responsible families who take summer boarders for a moderate compensation, and the probability that some of these families would prefer one or two permanent patient boarders to a number of sane boarders for a short season during the busiest portion of the year. A suitable system of visitation and of reports was advocated. The paper closed with the following summary of conclusions, to wit:

1. That inasmuch as many recoveries take place in asylums for the insane, it is to be expected that some convalescent patients may at any time be found in the wards.

2. That while, possibly, now and then a convalescent patient may be detained on probation an unnecessary period of time, such cases are not of frequent occurrence, nor important in their consequences when they happen, and that when they do occur the detention is very rarely indeed through criminal intent.

3. That many harmless incurables are unnecessarily detained in asylums for the insane; that these incurables would be happier in the enjoyment of ordinary family life and associations; and that systematic efforts should made to secure their enlogement, and their establishment under family care.

4. That under certain circumstances curable patients should be removed from asylum restraint and associations while yet uncured.

Owing to the lateness of the hour, the discussion upon Dr. Parson's paper was postponed until the next meeting of the Society.

CORRESPONDENCE.

MIDZU AME.

To the Editor of THE MEDICAL NEWS.

SIR: The inquiries received from physicians and druggists in the United States concerning midzu ame, and the attention that has of late been called to it by occasional articles in the medical press, lead me to think that a brief note on the subject may not be without interest to your readers.

Midzu ame is an extract of barley-malt and rice, in the proportion of about one part in ten, and hence may be termed a malted extract of rice. It is prepared by steaming the rice (a variety very rich in gluten called *mochigoine*) in perforated wooden boxes until fairly soft, when it is crushed and thoroughly mixed with the malt. After standing about twelve hours it is placed in hempen bags and the contained liquid forced out by strong pressure. This is then slowly evaporated to the consistence of a thick syrup, and, when ready for use, has a pale amber or amber-brown color, according to the care observed and amount of heat employed in its preparation.

Midzu ame has long been used by the Japanese as an article of diet for the sick, but not until within the last six or seven years has it been regarded as possessing medicinal properties. It is now employed as a medicine under the following conditions:

1. *In cases of indigestion arising from nervous exhaustion or infirmity.*

2. *As an adjuvant to other remedies in cases where food-medicines are required; e. g.*, with cod-liver oil emulsion, instead of barley-malt, in preparing the extractum malti ferrum, diluted with dialyzed iron, etc.

3. *As a nutrient and restorative in some exhausting diseases.* For this, a tablespoonful dissolved in hot water and added to a glass of rich milk makes a very nutritious and easily digested draught for the sick.

Very respectfully yours.

J. C. BERRY, M.D.

OKAYAMA, JAPAN, December 5, 1881.

NEWS ITEMS.

CINCINNATI.

(From our Special Correspondent.)

ARRANGEMENTS FOR THE SPRING COURSE have just been completed in both our Medical Colleges, and in both a new plan has been adopted. The didactic courses are to be recitative, instead of by the usual lecture-method. The plan appears to have many good features, and it is believed that by it the students will be stimulated to a better use of text-books, and at the same time acquire a better method of study than they would otherwise get. At the Medical College of Ohio, the Faculty have further decided to confine themselves entirely to clinical instruction, placing the didactic course in the hands of the adjuncts of the various departments.

THE COMMENCEMENT EXERCISES of the Miami College will occur Thursday evening, March 6th; those of the Ohio, Friday evening, March 7th.

A CASE OF SMALLPOX was discovered in the city last week. It is the first appearance of the disease for more than a year. The victim was a negro roustabout, who had contracted the disease in Louisville, where it has prevailed all winter. By the prompt action of the Board of Health, in sending the patient to the Pest-house, and vaccinating as many as possible of those with whom he had come in contact, no other cases have yet appeared. The Health Officer has also established a partial quarantine against Louisville. The railroads have been ordered to discontinue the transportation of rags, and officers have been stationed at the depots to inspect passengers and freight arriving from that source. It is said that the people of Louisville are much dissatisfied with such treatment, and advise that, if Cincinnati people are afraid of smallpox, they should vaccinate. But it has been only three years since the disease came to us from Louisville, and it then required nearly two years to free the city from it. During that time, too, the Health Board learned how difficult it is, in the absence of law, to enforce vaccination regulations, and for this reason they take the decisive steps referred to.

SCARLET FEVER.—A few cases of scarlet fever have also occurred. About two weeks ago, five or six inmates of the Children's Home were attacked at once. They were promptly removed, and further spread of the disease prevented.

A BILL TO REGULATE THE PRACTICE OF PHARMACY is now before the Legislature of Ohio. If passed, it will require that all pharmacists, whether graduates in pharmacy or not, be examined by a State board before being licensed to practice. It will not, however, govern those now in business. A petition urging the passage of the bill has been largely signed by physicians. Next in order should be a similar bill to regulate the practice of medicine.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.—This new Society was organized last Monday evening. Its object, as expressed in its constitution, is to promote the study of Neurology in all its departments. The meeting was fully attended by those physicians of Philadelphia and vicinity who are specially interested in nervous and mental diseases.

The following officers were elected:

President.—Dr. S. Weir Mitchell.

Vice-Presidents.—Drs. C. K. Mills and T. N. Kerlin.

Secretary and Treasurer.—Dr. Jas. Hendrie Lloyd.

Council.—Drs. S. Preston Jones, Wharton Sinkler, and J. T. Eskridge.

SURGEON-GENERAL WALES.—The term of office of Medical Director P. S. Wales, as Surgeon-General of the Navy, by virtue of his office as Chief of the Bureau of Medicine and Surgery, expired last week. The name of his successor has not yet been announced.

DR. FRANK H. HAMILTON'S work on *Fractures and Dislocations* has recently had a sixth revision and translation into French at the hands of DR. G. POINSOT.

THE ILLINOIS STATE BOARD OF HEALTH.—From the quarterly report of the Secretary of the Illinois State Board of Health, we learn that during the quarter ending December 31, 1883, the Board issued certificates entitling to practise medicine under the Medical Practice Act to eighty-six graduates upon diplomas from legally chartered medical institutions in good standing, and nine to practitioners on length of practice in the State; making in all 553 practitioners of medicine admitted to practice in Illinois during the year 1883. During the same period, 163 applications have been refused, and eleven certificates have been revoked; thus directly reducing the number of practitioners by 174, through the enforcement of the provisions of the Medical Practice Act.

Among the causes for refusal to issue certificates were the following: Presenting diplomas of institutions not recognized by the Board as in good standing; unsatisfactory personal or professional antecedents, habits, or associations, warranting the charge of unprofessional and dishonorable conduct; intent to practise in an unprofessional and dishonorable manner, as by claiming to cure incurable maladies; to possess unusual skill, experience, or facilities; and similar claims involving deceit and fraud upon the public. The revocations of certificates were in all cases based upon charges of unprofessional and dishonorable conduct.

Seven certificates were issued to midwives upon the credentials of recognized schools of midwifery, and four upon examination by the Board. A total of fifty-one midwives have thus been admitted to practice during the year—twenty-five upon credentials, seven upon length of practice in the State, and nineteen upon examination. In all forty presented themselves for examination, of whom twenty-one were rejected.

BARNUM'S WHITE ELEPHANT.—Barnum's white elephant, which has arrived in London and has been lodged in the Zoölogical Gardens, has excited quite a warm controversy. Prof. Flower says that the pink patches on the animal are due to an absence of coloring pigment in his epidermis. Mr. Balmano Squire says the patches are due to a skin disease. Mr. Sanderson, Superintendent of the Government Elephant Department in Bengal, asserts that the elephant does not differ from hundreds belonging to the Commissariat of the value of £150 to £200.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending January 19, 1884, indicate that remittent fever and diphtheria have increased, and that pneumonia, tonsillitis, consumption, bronchitis, and neuralgia have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending January 19, and since, at sixteen places, scarlet fever at eighteen places, and measles at thirteen places.

NOTES AND QUERIES.

THE METRIC SYSTEM.

To the Editor of THE MEDICAL NEWS.

SIR: Several letters have appeared in your columns discussing the relative merits of the metric and our present system in prescribing. Having been educated in a German university, I first studied the decimal system, but on commencing practice in a small town in Indiana, I found myself obliged to prescribe according to the old system, as the druggists neither understood the former, nor

had they the weights for dispensing. With this experience, I can safely assert that I consider the gramme system as far the simpler and easier of the two.

One of your correspondents justly observes that practitioners must get out of the way of thinking of doses in grains, etc., and accustom themselves to think of them in grammes and decimals of grammes. The Germans originally prescribed in grains, etc., traces of which you can even now see in their prescriptions; for example, in the following:

℞.—Morph. muriat., ... 0.06 (gr. j).
Sacch, alb., ... 4.0 —M.
Divide in pulv. No. vj.

If the prescriber had never heard of the old system, he would probably have written as follows:

℞.—Morph. muriat., ... 0.05
Sacch. alb., ... 4.0—M.
Divide in pulv. No. v.

which gives the same result, 0.01 of morphia, and is more in accordance with the principles of the decimal system.

Still, I do not think that this system will ever be universally adopted, until teaspoons, dessertspoons, wineglasses, etc., are abolished. Suppose the American Medical Association, or any other high medical authority, were to cause two standard doseglasses to be made, each containing 50.0 and 100.0 respectively, and and divided into ten and twenty equal parts respectively, each part (for convenience, I will call it "measure") would then contain 5.0, a trifle more than a teaspoonful. If these glasses were made in large quantities, they could be sold by the druggist for five cents, and dispensed with the prescription. Or graduated medicine bottles might be used, as now is the case in Great Britain. I will give two examples to illustrate my meaning. Suppose you wish to give, say twenty doses of sulphate of quinine, each containing 0.1. The prescription would read:

℞.—Quin. sulph., ... 2.0 (0.1 × 20).
Acid. sulphuric. dil., ... q. s.
Syr. limonis, ... 20.0
Aquæ. dest., . . . q. s. ad 100.0 (5.0 × 20).—M.
Sig.—One measure, in water, three times a day.

A second example:

℞.—Potass. acetat., ... 10.0 (2.0 × 5).
Sp. æther. nitrosi, ... 10.0 "
Infus. buchu, . . . q. s. ad 250.0 (50.0 × 5).—M.
Sig.—Ten measures, three times a day.

Here are five doses, each containing 2.0 potass. acetat., 2.0 sp. æther. nit., and 48.0 infus. buchu. It seems to me, nothing could be simpler, and it has the advantage of being mathematically accurate. The opponents of the system seem to have the wildest ideas of its complicacy, as is shown by a prescription in THE MEDICAL NEWS of the 3d of November, 1883, p. 503. As a matter of fact, it is never necessary to make use of more than two decimal places, except in prescribing drugs with very small doses, as atropia, strychnia, etc.

The most illiterate citizen understands the decimal system when applied to dollars and cents. Is it then too much to ask that educated and scientific men, as physicians are supposed to be, should understand the same system when applied to weights and measures?

I believe the idea of graduated glasses is now being entertained in Berlin; but there is no reason why a liberal country like the United States, which has always shown itself foremost in the invention and adoption of improvements, should not take the first step, and set an example to the old world, in simplifying the present method of prescribing, and at the same time rendering it safer, more accurate, and scientific.

I am, sir, your obedient servant,

A. C. WILLIAMS, M.D.

CINCINNATI, O., January 26, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 21 TO JANUARY 28, 1884.

ALEXANDER, CHARLES T., *Major and Surgeon.*—So much of Par. 7, S. O. 211, September 14, 1883, as directs him to report in person to the Commanding General, Department of the Missouri, for duty, is revoked, and he will, upon the expiration of his present leave of absence, proceed to St. Louis, Mo., and assume duty as Attending Surgeon and Examiner of Recruits in that city.—*Par. 1, S. O. 21, A. G. O.*, January 25, 1884.

ELBREY, FREDERICK W., *Captain and Assistant Surgeon.*—Present leave of absence extended six months.—*Par. 9, S. O. 24, A. G. O.*, January 25, 1884.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM OCTOBER 1 TO DECEMBER 31, 1883.

BAILHACHE, P. H., *Surgeon.*—Relieved from duty at Cape Charles quarantine station, October 13, 1883. Detailed as member of Board to examine candidates for promotion October 30, 1883. Granted leave of absence for thirty days, November 27, 1883.

HUTTON, W. H. H., *Surgeon.*—Granted leave of absence for twenty days, October 1, 1883.

WYMAN, WALTER, *Surgeon.*—Detailed as member of Board to examine candidates for promotion, October 30, 1883. To proceed to Norfolk, Va., to investigate the conduct of the service at that port, December 31, 1883.

LONG, W. H., *Surgeon.*—Leave of absence extended ten days, October 26, 1883.

MURRAY, R. D., *Surgeon.*—To proceed to Ship Island quarantine station, October 17, 1883. To inspect sites for quarantine stations, November 30, 1883. Granted leave of absence for twenty days, December 18, 1883.

SMITH, HENRY, *Surgeon.*—Granted leave of absence for twenty-five days on account of sickness, October 13, 1883. Relieved from duty at Norfolk, Va., October 17, 1883. To report to Surgeon Sawtelle, at New York, for temporary duty, November 27, 1883. Relieved from temporary duty at New York, and placed on waiting orders, December 31, 1883.

FISHER, J. C., *Passed Assistant Surgeon.*—When relieved by Assistant Surgeon Banks, to proceed to New York for duty, October 29, 1883. Granted leave of absence for thirty days, November 28, 1883.

GOLDSBOROUGH, C. B., *Passed Assistant Surgeon.*—Granted leave of absence for thirty-two days, on account of sickness, October 12, October 20, and November 1, 1883.

IRWIN, FAIRFAX, *Passed Assistant Surgeon.*—To proceed to Norfolk, Va., and assume charge of the service, relieving Asssistant Surgeon Glennan, October 16, 1883.

MEAD, F. W., *Passed Assistant Surgeon.*—To proceed to Portland, Oregon, to inspect the service, and report the condition of Assistant Surgeon Devan, December 5, 1883. To return to station, Port Townsend, Washington Territory, December 18, 1883.

COOKE, H. P., *Passed Assistant Surgeon.*—To proceed to Charleston, S. C., for duty, November 27, 1883.

BANKS, C. E., *Assistant Surgeon.*—Detailed for temporary duty at Georgetown, D. C., October 11, 1883. Granted leave of absence for thirty days, October 12, 1883.

BENNETT, P. H., *Assistant Surgeon.*—Placed on waiting orders, December 15, 1883. Granted leave of absence for thirty days, December 22, 1883. Upon expiration of leave of absence, to proceed to Detroit, Mich., for duty, December 29, 1883.

PECKHAM, C. T., *Assistant Surgeon.*—To proceed to Wilmington, N. C., and assume charge of the service, relieving Passed Assistant Surgeon Irwin, October 16, 1883.

DEVAN, S. C., *Assistant Surgeon.*—Granted leave of absence for ninety-five days, on account of injury and sickness resulting therefrom, November 15, December 5 and 22, 1883.

BEVAN, A. D., *Assistant Surgeon.*—To proceed to Portland, Oregon, and assume charge of the service, December 29, 1883.

GLENNAN, A. H., *Assistant Surgeon.*—To proceed to New Orleans, La., for duty, October 17, 1883.

WASDIN, EUGENE, *Assistant Surgeon.*—To proceed to Mobile, Ala., for temporary duty, October 11, 1883. To proceed to Galveston, Texas, for temporary duty, November 17, 1883.

PROMOTIONS.

BENSON, J. A., *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from October 1, 1883, October 4, 1883.

BANKS, C. E., *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from November 1, 1883, to November 6, 1883.

THE VALUE OF INTERNAL ŒSOPHAGOTOMY IN THE TREATMENT OF CICATRICIAL STRICTURE.[1]

BY HENRY B. SANDS, M.D.,

PROFESSOR OF THE PRACTICE OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; SURGEON TO THE ROOSEVELT HOSPITAL.

My object in the present paper is to consider the value of the operation known as internal œsophagotomy; and to give the particulars of an aggravated case of stricture lately under my care, in which this procedure was carried out with a gratifying amount of success. My remarks will relate only to that form of stricture denominated simple, fibrous, or cicatricial, inasmuch as the operation in question is one of doubtful utility in cases of stricture due to the development of a malignant growth.

Simple stricture of the œsophagus is probably always preceded by inflammation or ulceration of one or more of its component layers. Systematic writers describe a number of varieties of inflammation, such as catarrhal, syphilitic, phlegmonous, and traumatic, any one of which may lay the foundation of stricture. From an etiological point of view, however, œsophageal strictures are distinguished by the fact that a vast majority of them are due to the reactive inflammation which follows contact with some highly corrosive liquid, such as sulphuric, nitric, or hydrochloric acid, or a concentrated solution of caustic potash. A consideration of the effects produced by these substances, when accidentally or intentionally swallowed, is essential to a correct appreciation of the pathology and treatment of the lesions that may ensue. These effects vary greatly in different cases, according to the amount of the liquid taken and its degree of concentration. They may be limited to a part or the whole of the œsophagus, or may also extend to the stomach. If the poison is undiluted, and the quantity large, death usually occurs soon after the injury, in consequence of sloughing inflammation of the œsophagus. The slightest lesion observed consists in a destruction of the epithelial lining, which is soon cast off and regenerated. The cases that possess a surgical interest lie between these extremes. The destructive action may be restricted to the œsophageal mucous membrane, or may involve the subjacent connective tissue, or even the muscular coat. It may be confined to a very short portion of the tube, or may extend throughout its entire length. Furthermore, it may include a part or the whole of its circumference. Accordingly, when the substance which has been destroyed and cast off is replaced by adventitious fibrous tissue, one or more strictures will result, varying in situation, character, and extent. Avoiding details which are familiar to all, or which are irrelevant to the present discussion, I would draw attention to certain points of contrast between several recognized varieties of stricture, which have an important relation to the prognosis and treatment of the disease. *Cæteris paribus*, the gravity of a stricture will be greater in proportion to its length; and when we remember that a narrowing of any considerable portion of the length of the œsophagus rarely takes place unless the corrosive action of the poison has been intense; and that the long, tubular strictures which result therefrom are usually dependent upon the production of an abundant quantity of cicatricial tissue, and are correspondingly narrow, indurated, and unyielding, as well as often tortuous, we can understand why, as a rule, such strictures are amenable neither to dilatation nor to internal division, but demand gastrostomy as the only available means of prolonging life.

Provided a stricture is permeable to instruments of moderate size, its length can usually be ascertained by the use of a bulbous bougie. The upper limit is indicated when the bulb meets with resistance before it enters the stricture, and the lower limit as it again encounters resistance on being withdrawn. Œsophageal strictures, as I have already stated, vary greatly in their longitudinal extent; and, classified according to their variations in this respect, they may, like strictures of the urethra, be spoken of as linear, annular, or tubular. Another variety of stricture is that in which the cicatricial tissue is of limited horizontal extent, so that it does not embrace the entire circumference of the œsophagus. It may thus form a more or less rigid, valve-like projection against the opposite unaltered wall, causing the orifice of the stricture to have an eccentric position. Trélat,[1] in 1870, proposed to diagnosticate this peculiar condition by means of a demi-bulbous bougie, whose expanded extremity is flat on one side and convex on the other. By introducing the bulb beyond the stricture, and presenting its convex surface toward different parts of the circumference of the œsophagus while making successive attempts to withdraw it, the situation of the callous deposit may be determined by feeling the greater resistance which it opposes to the withdrawal of the instrument. The practical application of the information thus obtained will presently be apparent.

Perhaps I can adopt no better plan of stating my own views regarding the value of internal œsophagotomy as a surgical expedient than by combining them with the record of a case in which I have recently performed the operation.

Addie B., aged eight years, came under my care on January 10, 1883, having been sent to me by

[1] Read before the New York Surgical Society, Jan. 22, 1884.

[1] Bulletin de Thérapeutique, Paris, 1870, p. 262.

Prof. William H. Doughty, of Augusta, Ga., in the hope that something might be done to relieve her of an œsophageal obstruction which had been caused by the accidental swallowing of a mouthful of a strong solution of caustic potash, on September 27, 1882. No alarming symptoms immediately followed the accident, but deglutition was always afterward more or less difficult and painful, rendering necessary a fluid diet, which consisted chiefly of milk. Dysphagia began to be severe early in November, and was attended with rapid emaciation, the child's weight having been reduced from forty-four to forty-one pounds in the week ending November 16. Subsequently a slight improvement took place, but toward the end of December the patient's condition grew very alarming, and it was found necessary to resort to rectal alimentation. Early in January, dilatation of the stricture was attempted; no progress was made, however, and fearing that the child's situation might at any time become desperate, Dr. Doughty recommended that she should be brought to New York for the purpose of being benefited, if possible, by surgical treatment. At the time of my first visit, on January 10, I found her very weak, emaciated, and dejected, and evidently threatened with death from starvation. Deglutition had become almost impossible, and the rectum had become somewhat intolerant of enemata. On exploring the œsophagus, I discovered a tight stricture, situated nearly opposite to the middle of the sternum, at a distance of eight and a half inches from the incisor teeth. The stricture was impassable to instruments, and the daily attempts I made to penetrate it were unsuccessful, until January 16, when I was able to introduce a filiform whalebone bougie, having a diameter of two-thirds of a milimetre. During the ensuing five months, dilatation was practised almost every day, but made very slow progress, as is shown by the following record:

January 23.—Passed an elastic bougie, No. 6.
February 1.—Passed No. 9.
22d.—Passed No. 11.
28th.—Passed No. 12.
March 15.—Passed No. 13.
April 11.—Passed No. 14.
27th.—Passed No. 15.
May 8.—Passed No. 16.
28th.—Passed No. 17.

On February 1, I succeeded in introducing an elastic catheter, having a diameter of three millimetres, which proved large enough to allow the injection of milk into the stomach, whenever the child was unable to swallow. Until this time her condition had been extremely precarious, and the question of performing gastrostomy was more than once debated. But, on the one hand, the patient seemed too feeble to bear the operation; and, on the other, her father's repugnance to such a procedure was invincible. Later, the dysphagia diminished, so that she was able to swallow an abundance of fluid food, consisting of milk, soup, and raw eggs; and towards the end of May it was found that she had gained twelve pounds in weight since her arrival in New York. Nevertheless, it had meanwhile become evident that the stricture was of the most obstinate character; for, whenever a single day passed without an attempt to dilate it, a contraction would take place, rendering necessary the use of smaller instruments, the employment of which sometimes caused considerable pain. Being convinced that future treatment by dilatation would be useless, and perhaps dangerous, by allowing accidental injury to the œsophagus, I decided to resort to internal œsophagotomy, as the most promising expedient under the circumstances. I was encouraged to anticipate success from the operation in the present case, especially in view of two considerations: *First.* I had ascertained by careful exploration, made with demi-bulbous bougies, that the stricture was due to the pressure of a narrow ring of fibrous tissue, occupying only a quarter of an inch of the length of the canal. *Second.* On introducing beyond the stricture an instrument which I designed for the purpose of examining the deeper parts of the œsophagus, and which is constructed on the same principle as Dr. Weir's urethrometer, I found that when the bulb was expanded to its utmost limit, No. 28 (F.), no other contraction could be detected. Accordingly, it appeared probable that great benefit must result from internal division of the stricture, provided this could be safely accomplished. But the operation is well known to be hazardous; and perhaps, for this reason, it has been rarely undertaken since it was performed for the first time by its inventor, Maisonneuve, in 1861.[1] Mackenzie,[2] who published, a few months ago, an interesting article containing the statistics of internal œsophagotomy, was able to cite only eleven cases in which the operation had been performed for cicatricial stricture; and of these, three, or 27.27 per cent. proved fatal. The operation is condemned by many surgical writers, and is not even mentioned in some of our popular text-books. When we reflect, however, that the natural termination of the disease is death by starvation; that there are many cases like the one herewith reported, which baffle the most patient attempts at dilatation; that the operation required to establish an artificial opening in the stomach for the purpose of feeding is one which is likewise dangerous, and which, even when successful, places the patient in a deplorable condition, and cannot be contemplated without some feeling of disgust; and that, finally, internal œsophagotomy is an operation which aims to reëstablish a function so important as that of deglutition, we must acknowledge that it merits the most attentive study, with the view of determining the class of cases to which it is applicable, and of adopting the safest and most efficient method of performing it. Undoubtedly, the cases most favorable for the operation are those in which there is only a single stricture, of slight longitudinal extent. Conversely, little hope of benefit from it can be entertained when the stricture is long, tortuous, and indurated. We notice here a close analogy between strictures of the urethra and those of the

[1] Maisonneuve, Clinique Chirurgical, Paris, 1864, tome ii. p. 409.
[2] American Journal of Medical Sciences, 1883, vol. i. p. 420.

œsophagus. In bad cases of urethral stricture, however, which are not curable by internal division, we can often resort with success to external urethrotomy; while external division is a procedure very rarely adapted to œsophageal strictures, on account of the usually inaccessible situation of the affected parts.

The dangers of internal œsophagotomy depend on the important relations of the gullet. In different parts of its course it is in close proximity to the pneumogastric and the recurrent laryngeal nerves, the trachea, the left bronchus, the pericardium, the aorta, the azygos vein, and the pleura. The loose connective tissue behind the œsophagus is prone to suppurate when injured, or when food or other irritating substances come in contact with it. Some of the risks attending the operation may be gathered by a perusal of the recorded cases. In Maisonneuve's hands, two proved fatal from peritonitis, apparently not dependent on the operation, as, at the autopsy, the incisions were found not to have passed beyond the limit of the callous tissue, while the surrounding parts were free from inflammation. Braun[1] conjectures that in both these cases the stomach may have been accidentally perforated by the metal conductor which forms a part of the œsophagotome, although Maisonneuve alleges that no such perforation could be discovered on careful examination. Trélat's[2] patient had severe hemorrhage after the operation; and death, in a case related by Schilz, was probably due to this cause. In Czerny's case, the incision doubtless perforated the œsophagus; for emphysema of the neck was noticed a few hours subsequent to the operation, and, after death, a large abscess was discovered in the posterior mediastinum, communicating with the œsophagus and with the right pleural sac. Likewise, in a fatal case recorded by Mackenzie, pneumonia supervened soon after the operation, and at the autopsy a purulent collection was found in the right pleura. Omitting further allusion to Maisonneuve's cases, in which there is no demonstrable connection between the fatal event and the operation, it is evident that the chief danger of internal œsophagotomy is either that of accidentally cutting the healthy vascular tissue, thereby causing hemorrhage, or of making the incision so deep as to injure one or more of the important parts with which the gullet is in relation. An ideal operation, therefore, would be one in which the cicatricial tissue alone is divided, and in which the periœsophageal structures are left intact. We are thus left to examine the different methods which have been employed, in order to ascertain to what extent these requirements have been fulfilled.

Maisonneuve's instrument is similar in principle to his well-known admirable urethrotome. It has a conductor, consisting of a slender, flexible bougie, to which is attached a flattened steel guide, four millimetres in breadth, and grooved on opposite sides to receive the blades. The latter are two in number, each one being twelve millimetres in breadth, of triangular shape, and having a cutting edge limited to its anterior third, the remainder being quite blunt. The guide having been introduced through the stricture into the stomach, one of the blades, the edge of which is directed laterally, is passed slowly and gently along the conducting groove until it reaches the stricture, when it is advanced with a sufficient degree of force to overcome the resistance. The second blade is then introduced in the same manner, making an incision through the opposite side of the stricture; finally, the entire instrument is carefully withdrawn.

Studsgaard employed an instrument resembling Maisonneuve's, but having a concealed double-edged blade.

Lannelongue's œsophagotome also resembles Maisonneuve's, but has only a single blade, which is protected by a sheath. The projection of the cutting edge is fifteen millimetres.

Trélat invented an instrument by which he divided the stricture by cutting from below upward. It is provided with two blades, each one being four centimetres in length, concealed within a metal tube four millimetres in diameter and six centimetres in length. By turning a screw in the handle of the instrument, the blades can be projected to any distance not exceeding two centimetres. Owing to the length of the blades, they have a very gentle slope, which facilitates their passage through the tissues that require to be divided.

Dolbeau operated by the retrograde method, using an instrument provided with a conical tip, in which were concealed two lateral cutting blades. The bulb was made just large enough to pass through the stricture, and the blades could not be projected beyond the diameter of the cone.

Czerny and Mackenzie have also performed the retrograde operation with instruments of their own invention, each one being furnished with a single blade.

On comparing these several instruments, it will be found, in the first place, that some are arranged so as to cut from above downward, while with others the incision is made from below upward. Recent writers have usually, and perhaps rightly, condemned all instruments belonging to the former category; but their objections do not seem to me the strongest that might be offered. Whether the incision is made from above downward, or in the contrary direction, is of itself a matter of little moment. It has been said that when the incision is made by thrusting the knife downward, the œsophageal wall below the stricture is especially liable to be perforated; but I cannot understand why this should happen without carelessness on the part of the operator, nor am I acquainted with any clinical or pathological evidence in support of the assertion. The great disadvantage of the anterograde operation seems to be the necessity of introducing a sharp metallic guide considerably beyond the stricture before the blade can be safely used. This manœuvre was found to be extremely difficult by both Maisonneuve and Lannelongue, and must be attended with no slight risk of causing perforation. In operating by the retrograde method, this danger is diminished by the flexibility of the in-

[1] Czerny; Beiträge zur Operativen Chirurgie, p. 76.
[2] Bulletin de Thérapeutique, 1870, p. 259.

strument employed, as well as by the circumstance that its extremity can be made blunt, and need not be introduced far beyond the seat of stricture. On the other hand, in the case of a stricture of very small calibre, Maisonneuve's operation would have the advantage that it could be performed with a guide not exceeding two millimetres in diameter; while an instrument intended to cut from below upward can hardly be made with a diameter less than four millimetres.

A second difference to be noticed is, that some instruments are provided with only a single blade, while others have two blades so arranged as to cut on opposite sides. There can be no doubt that the safety of the operation is increased when only one blade is employed, which can be directed with precision toward any part of the circumference where division of the cicatricial tissue is indicated.

The last and most important contrast to be observed, is the different depth to which the incision is extended, or may be extended, with different instruments. This is very great, Dolbeau's instrument, for example, being so constructed as to permit of mere scarification; while in that employed by Trélat, the distance between the cutting edges of the two blades, when fully projected, is two centimetres. In endeavoring to estimate the relative value and safety of shallow and deep incisions in the treatment of stricture of the œsophagus by internal division, we must take into account certain facts revealed by pathological anatomy. It is well known that, in strictures of equal calibre, the thickness of the fibrous material on which the constriction depends varies greatly in different instances. Thus, a stricture which will admit only a filiform bougie may be owing to the presence of a narrow ring of cicatricial tissue, not exceeding one or two millimetres in thickness; while in another stricture of the same calibre, the thickness of the constricting band may exceed a centimetre. It is evident that in the former case a shallow incision would relieve the constriction, and that in the latter a deep incision would be required for the same purpose. It is also plain that, in the former case, a deep incision would be liable to extend beyond the outer circumference of the œsophagus. Indeed, this accident occurred and proved fatal in Czerny's patient, although the incision was only two millimetres in depth. Unfortunately, we have no means of determining in the living subject the exact thickness of the callous deposit, and are consequently left in uncertainty regarding the needful depth of the incision in any given case. A shallow cut may be useless; a deep one may be fatal. Notwithstanding our want of knowledge as to the condition of the diseased parts, we may, I think, proceed in such a manner as to overcome the constriction without subjecting the patient to any extraordinary risk. As, in spite of every precaution, the edge of the knife may possibly be directed against some part of the œsophagus which has undergone no morbid change, the depth of any single incision ought to be a trifle less than the thickness of its coats, which sometimes does not exceed two millimetres. Assuming that the stricture is annular, we may make a superficial incision at any point of its circumference, and afterward endeavor to effect dilatation by the introduction of sounds. If we have succeeded in dividing the whole, or even the greater part, of the constricting band, rapid improvement will probably follow. Should little or no benefit result from the first incision, a second one may be made at some other point, where perhaps the ring may be thinner and less resistant. In case this fails to cause improvement, still another point may be selected for incision, with perhaps a more fortunate result; or it may be found expedient to make a number of incisions in the same plane. Much has been said respecting the comparative safety of cutting in different directions; some operators preferring to cut toward the right side, some toward the left side, while others regard a posterior incision as the only proper one. The relations of the œsophagus vary so considerably in different parts of its extent, that it is impossible to lay down any rule which would apply to all cases. Perhaps, in a general way, it may be affirmed that an anterior incision is the most hazardous, and a posterior one the least so; but if we adopt the precaution of avoiding incisions of sufficient depth to penetrate the entire thickness of the œsophageal wall, we may turn the edge of the knife toward any point without running much risk of wounding important parts.

The most difficult problem connected with the operation is that of exactly regulating the depth of any given incision. I believe that this can be done only by distending the stricture at the time when the knife is applied to it. On this principle I have devised the simple œsophagotome represented in the accompanying figure.

The shank of the instrument, which is fifteen and a half inches in length, and four millimetres in diameter, is a flexible tube made of narrow spiral steel plate, secured within by two pieces of fine wire in order to prevent separation of the spiral coil. The instrument is provided with a variable number of steel bulbs, each bulb being furnished with a corresponding knife-blade. The bulb is firmly fastened by a screw to the distal end of the shank, and the knife is attached to an inner flexible steel rod, manipulated by a thumbscrew at the proximate end of the instrument. By turning this screw, the knife is drawn out from its concealed position within the bulb, the back of the blade sliding over a firm inclined plane. An index on a dial plate indicates the amount of projection of the blade, the maximum projection being two and a half millimetres. A small sliding ring on the spiral

tube is used to indicate the distance of a stricture from the incisor teeth. I selected the metallic spiral tube for the shank of the instrument because it combines flexibility with strength. The bulb being conical, the operator can readily perceive when it comes in contact with the stricture, before he projects the blade. In operating, a bulb must be employed which exactly fits the stricture; the depth of the incision will then just equal the distance to which the blade is projected by the action of the screw in the handle.

The subsequent progress of the case may be given in the following brief extracts from my note-book:

June 15.—Stricture contracted to 15 (F.). Introduced œsophagotome with bulb No. 15. Passed bulb-joint beyond the stricture; projected blade two and a half millimetres, and incised the resisting tissue in the posterior median line. The operation was nearly painless, and only a few drops of blood followed the incision. The wound was allowed to remain undisturbed for twenty-four hours, the patient meanwhile being nourished by rectal enemata. These seemed to cause pain in the abdomen, and were therefore discontinued on the day after the operation, the child being permitted to swallow milk, which she did without pain. On the same day dilatation was resumed, and the stricture was found to admit No. 19.

26th.—Daily introduction of elastic bougies since the last date has failed to accomplish any further dilatation. Incised stricture on right side to a depth of two millimetres, using bulb No. 19.

29th.—Nothing having been gained by the last operation, the same instrument was introduced, and an incision, two and a half millimetres, was made obliquely backward and toward the left side. Considerable resistance was offered to the knife, and much soreness followed the operation, rendering dilatation unusually painful. Although a very few drops of blood escaped when the incision was made, the bougies used during the succeeding week were always found stained with blood on being withdrawn.

July 12.—Dilatation arrested at 23. Arming the œsophagotome with a bulb of this size, introduced it as before, and made an incision, backward and toward the right side, two millimetres in depth. The knife encountered very little resistance, and the operation was followed by slight hemorrhage, the blood expectorated being about half an ounce.

23d.—Dilatation has reached No. 26, and patient is allowed for the first time to take solid food, which she swallows without difficulty. It may be remarked, incidentally, that no subsequent trouble was experienced in swallowing ordinary food.

August 1.—Dilatation has not gone beyond No. 27. With bulb of this size made an incision in posterior median line; depth two millimetres.

20th.—Dilatation reached 31 on August 12, but treatment having been suspended for a week, it was ascertained that the stricture had contracted to 27. To-day, using instrument with bulb 27, incised in posterior median line to a depth of two millimetres. I had now determined to make all the incisions that might be required, as far as possible, in the same plane, with the object of gradually and safely effecting a complete division of the stricture tissue, or of rendering it so thin that it would offer no obstacle to dilatation.

October 7.—Limit of dilatation, 34. Since last date, treatment was once suspended for eighteen days, when contraction took place from 34 to 26. Made an incision in posterior median line with bulb 34, projecting the blade two millimetres.

31st.—Dilatation reached 39, beyond which point it was not thought best to carry it.

November 19.—Patient started for home, being in excellent health, and weighing sixty-two and a half pounds, a gain of twenty-one and a half pounds since treatment was commenced, nine months ago.

In a letter dated January 4, 1884, Dr. Doughty writes that "there is no evidence of a tendency to recontraction, and the function of the œsophagus is as perfect as it was before the injury was inflicted." Bougies are still employed, however, in the hope of obtaining a radical cure. I have neglected to state that, before the child left New York, there were signs of catarrhal inflammation in the neighborhood of the stricture, the bougies when withdrawn being stained with a little pus. This symptom has since disappeared.

I am not willing to assert that, in the case I have narrated, a permanent cure has been effected; but I think it may be affirmed that the treatment pursued has been successful in preserving the child's life, and in restoring her to comparative health and comfort. Should dilatation fail to prevent recontraction, I would not hesitate to resort again to internal œsophagotomy.

The limit of this paper forbids any attempt to consider fully the general subject of treatment of cicatricial narrowing of the œsophagus; yet a brief enumeration of the several methods at our disposal may be profitable, by helping us to estimate the relative value of the operation now under discussion.

1. Gradual dilatation is usually, and in my opinion, justly regarded as the safest and best mode of treatment, wherever it is practicable. It is much to be regretted that this method is not always resorted to as a preventive measure, or in the incipient stage of the disease, before cicatrization has taken place. It is a fact, however, that the surgeon's aid is rarely sought until a stricture has become narrow, and deglutition difficult. I have little doubt that, in many cases, the formation of a stricture might be obviated by the frequent introduction of a full-sized bougie while the healing process is going on; and I believe it should be the rule to commence such treatment within a week or ten days after the injury has been received.

If a stricture is impermeable to instruments, dilatation is of course impossible; but, even when bougies can be readily inserted, dilatation is not always successful, as some have maintained, in restoring the distensibility of the contracted parts. This fact is well shown in the case I have described, in which this treatment was faithfully pursued during the long period of five months. Nor is the introduction of dilating instruments always safe,

especially when the stricture is narrow. I am able to recall two cases occurring in my own practice, in which an abscess was caused by what I thought at the time to be a cautious use of an elastic bougie. One of these patients recovered; the other died, the fatal event being partially attributable to an accidental perforation of the œsophagus, which led to deep-seated suppuration. A similar accident occurred in the hands of Maisonneuve, who perforated the œsophageal wall with a hollow sound; and, believing that the instrument had entered the stomach, he injected a quantity of beef-tea into the posterior mediastinum, causing the patient's death on the following day.

Finally, treatment by dilatation often requires to be continued indefinitely, in order to prevent recontraction; and, as in the case of urethral stricture, persons suffering from stricture of the œsophagus are notoriously prone to neglect themselves, avoiding dilatation until it becomes difficult or impossible.

2. I have already stated at some length what I believe to be the indications for performing internal œsophagotomy. The operation has been too warmly advocated by some who have succeeded with it, and too often depreciated by others who lack the experience needed to give weight to their opinions. The number of cases in which the operation has been performed is so small that its value cannot be determined by statistics; but the recovery of nine out of twelve patients in whom this procedure has been carried out with beneficial results, suffices to shield it from condemnation, and to claim for it serious consideration. The case I have recorded is an example of the class in which the operation may be regarded as proper. When the stricture is narrow, yet permeable; is of slight longitudinal extent, not exceeding, perhaps, a centimetre, and cannot be dilated to a size sufficient to permit easy deglutition, I believe the operation of internal œsophagotomy to be the most hopeful expedient at present within our reach. I admit that it cannot be performed without some risk, which, indeed, it may be impossible to estimate; but this is warranted by the hopeless character of the disease, and by the results of the alternative operation of gastrostomy. Perhaps the dangers attending it may be diminished by proceeding in the cautious manner I have described, so as to avoid injuring any of the important parts which lie outside of the œsophagus. The amount of benefit to be derived from the operation will depend on the form and extent of the existing lesion. If the stricture is occasioned by a narrow ring of fibrous tissue, or by a valve-like membrane, a radical cure will probably ensue when this has been divided.[1] In most cases, however, the operation will prove only an aid to dilatation, rendering this practicable, and perhaps occasionally successful in accomplishing a radical cure. In proportion to the length and induration of the stricture, the utility of internal œsophagotomy will diminish, and in many cases it would be obviously unwise to attempt it.

[1] Vide Case by Roe, New York Med. Record, vol. xxii. p. 538.

3. Boeckel[1] has recently reported two cases of impermeable stricture which he claims to have cured by electrolysis. An œsophageal tube, armed at its distal extremity with a small ball of copper, was introduced down to the stricture and then connected by means of a wire with the negative pole of a galvanic battery; the plate connected with the positive pole being placed over the eighth rib, a little to the left of the spinal column. In one case, after three applications of from two to five minutes' duration, a bougie, No. 13, was passed through the stricture, which, after the tenth application, readily yielded to dilatation. In the other case, a bougie No. 6 entered the stricture after a single application, large bougies passing at every subsequent sitting. I am unable to determine the value of this novel method of treatment, but am inclined to consider as dangerous any such attempt to penetrate a stricture which will not admit a guide.

4. Strictures situated in the region of the neck, which are either impassable or cannot be dilated, have been sometimes treated by external œsophagotomy, the operation having usually been undertaken with the view of establishing a fistula through which the patient may be fed by means of a stomach-tube introduced through the fistula, and into the stomach. Mackenzie[2] has collected five cases, in four of which the operation was followed by death at periods ranging from twenty-two hours to eight days. The fifth patient (Bryk's)[3] is reported as having been alive at the end of seven weeks. A later account of this patient, however, is given by Von Mosengeil,[4] who states that the case terminated fatally, from pyæmia, six months after the operation. In this case the œsophagus was opened above the stricture, which was three and a half centimetres in length, and was situated just below the level of the upper border of the sternum. It was treated by dilatation, and could be passed only by instruments introduced through the fistula; these caused severe pain, frequent hemorrhage, and finally a deep-seated abscess. In another case (Horsey's)[5] the œsophagus was likewise opened above the stricture, which was found to be impassable. No encouragement, therefore, is offered to repeat this operation with the object of establishing a permanent fistula, as there is no certainty that an opening can be made below the seat of obstruction. If the patient is doomed always to be fed through an artificial opening, gastrostomy is the operation which should be selected, as it secures a ready access to the alimentary canal below the stricture, and places the fistula in a situation where it can be easily hidden from view.

But evidence can be brought to show that external œsophagotomy may be of great service by enabling us to deal successfully with strictures that are impermeable to instruments introduced through the mouth. Within the past year Gussenbauer[6] has

[6] Zeitschrift für Heilkunde, Bd. iv, 1883, p. 33.

published an account of two cases of deep-seated stricture, in which he achieved success by a method he calls combined œsophagotomy. The first case was that of a woman, twenty-six years old, who suffered from a tight stricture caused by swallowing sulphuric acid. The stricture extended from the cricoid cartilage to the bifurcation of the trachea, and at the time of the operation was impassable to all instruments introduced through the mouth. The œsophagus was laid open by an external incision; and, when the margins of the wound were held apart, the operator passed a probe downward a distance of eight centimetres, when it was arrested at the point of greatest constriction, opposite the tracheal bifurcation. He finally succeeded in passing through the stricture a probe one millimetre in diameter, and then a very fine grooved director, upon which, with a narrow-bladed herniotome, he incised the cicatricial tissue in two directions, namely, forward toward the right, and forward toward the left side. An elastic catheter, eight millimetres in diameter, was now introduced through the wound and into the stomach, and was retained until the fifth day, for the purpose of increasing the dilatation of the stricture, and of injecting fluid food. It was then removed, and, until the fistula closed—three weeks after the operation—the patient was fed by means of a stomach-tube introduced through the mouth. A week later, when she left the hospital, she could swallow solids without difficulty, and could herself readily pass a bougie twelve millimetres in diameter. Neglecting to follow the advice she had received, to continue treatment by dilatation, she returned to the hospital three months subsequently in the same condition as that first described; so that the operation had to be repeated. The wound in the neck healed at the end of three months; and, when the patient was last seen—fourteen months after the operation—the stricture admitted a bougie twelve millimetres in diameter. During this interval, however, she had suffered considerably in consequence of failure to practise frequent dilatation; and it seemed probable that this treatment would be required indefinitely, in order to guard against a recontraction.

The second case was that of a child, two and a half years old, who had become greatly reduced in consequence of a stricture due to the action of carbolic acid, which had been swallowed two weeks after birth. Before the operation, a bougie, three millimetres in diameter, was arrested at a point one centimetre below the cricoid cartilage. One, two millimetres in diameter, descended to the level of the manubrium sterni, while no instrument could be made to enter the narrow constriction which was near the cardiac orifice. By an operation like the one already described, the stricture was incised; the incision in the cardiac stricture, which lay nine centimetres below the opening in the neck, being two millimetres in depth, and six millimetres in length. The external wound closed in thirty-five days; dilatation was practised; and when the child was discharged from the hospital, a week afterward, she was able to swallow solid food, and a bougie having a diameter of ten millimetres could be passed into the stomach. After the lapse of a year, when the case was reported, the patient still remained well, dilatation being continued by passing bougies once a week.

A third case, in which a similar operation was successfully performed, has just been recorded by Bergmann.[1] In this instance the stricture, which was caused by the action of oxalic acid, was situated in the neck at the level of the third tracheal ring. The patient was an adult; and, although before the operation the stricture appeared to be impermeable, it was successfully penetrated after the parts were exposed to view, and the division of a valvular cicatricial fold with a tenotomy knife enabled the operator to pass a full-sized œsophageal bougie into the stomach. The opening in the neck healed at the end of five weeks, and the patient, when exhibited three months after the operation, at a meeting of the Berlin Medical Society held last October, was able to pass easily a full-sized bougie.

5. Gastrostomy, when performed merely with the intention of establishing permanently an artificial opening in the stomach, is at present regarded with considerable favor; but it can never be anything more than a last resort in cases otherwise hopeless. Alsberg's[2] statistics, which are the most complete I have been able to find, show that gastrostomy has been performed in nineteen cases of cicatricial stricture. Ten of these patients died within the first few days, mainly from peritonitis; four survived, respectively, seven, eight, fifteen, and eighteen months; while five were supposed to be living at the time of the report. Probably these are the cases alluded to by Lefort,[3] who has recently said that five persons were known to be alive at the following periods after operation, namely, four and a half months, eight months, twenty months, two years, and three years. These results justify a resort to the operation in certain cases; and it is reasonable to hope that, with increasing experience, the percentage of mortality attending it may be considerably reduced.

6. Finally, within the past year, Bergmann[4] has achieved a brilliant success in the treatment of a deep-seated stricture by a method which is both ingenious and original. Already Schede had proposed, and Trendelenburg had attempted, but in vain, the dilatation of an œsophageal stricture by means of instruments introduced through a gastric fistula previously established. Bergmann's patient was a man, forty years of age, who had an impassable stricture forty centimetres from the incisor teeth, due to the action of caustic potash. Gastrostomy was performed on January 29, 1883, and recovery took place without accident; but it was found impossible to prevent a constant escape of the contents of the stomach, and the patient's condition seems to have been very miserable. It was therefore determined to attempt the removal of the stricture. After several trials, the œsophagus was successfully explored by introducing a sound through

[4] Deutsche med. Wochenschrift, October 24, 1883.

the mouth while the forefinger was pushed upward through the cardiac orifice; a membranous septum was then discovered, separating the sound from the finger. This was too thick and firm to allow safe and easy perforation by the sound; while the close proximity of the heart and the descending aorta forbade an attempt to divide it with a knife. The obstructing membrane was at last safely perforated by the compressing action of a metal clamp, the blades of which were passed through the cardiac orifice to the seat of stricture, and made to grasp the end of the sound, this being pressed against the septum so as to bring it between the jaws of the clamp. Perforation having been accomplished, the opening was dilated, at first with pieces of compressed sponge, and afterwards with sounds, until it admitted a bougie one inch in diameter. On May 21, the artificial opening in the stomach was closed by a plastic operation, the function of deglutition having been completely restored. The patient, when exhibited on October 10, was in excellent health, and was able to introduce a full-sized sound into the stomach. Meanwhile, treatment by dilatation was being continued.

On reviewing the whole subject, we may conclude that certain forms of œsophageal stricture, which have heretofore proved unmanageable, are no longer beyond the reach of surgical art; and that, in some of these, internal œsophagotomy is capable, not only of saving life, but also of reëstablishing the function of deglutition, so essential to its enjoyment.

MEDICAL PROGRESS.

TREATMENT OF CANCER OF THE RECTUM.—At the close of a recent lecture on this subject, PROF. TRÉLAT drew the following conclusions:

1. Cancers of the rectum which do not cause accidents should be left alone.

2. Cancers of the very extremity of the rectum, or of the margin of the anus, should be extirpated.

3. Accidents should be treated as they arise, but palliative measures are to be avoided. In this respect, he is in accord with Prof. Verneuil, but opposed to many English surgeons.

4. When the finger can be passed beyond the cancerous mass, rectotomy should be performed, otherwise not; but a way of derivation should be made by lumbar colotomy or by forming an inguinal anus.—*Revue de Thérap.*, January 15, 1884.

TREATMENT OF BUBOES.—M. KEMPEN recommends multiple punctures with a lancet, plunged deeply into the bubo. The punctures should be made early. The result is very gratifying; in many cases, even before pus forms, the inflammatory tension disappears, and resolution proceeds rapidly. In case pus has formed, it is pressed out, and an injection of a 1–12 solution of chloride of zinc made into the bubo. A dressing of dry charpie is used.

When the bubo has already reached the suppurative stage, it is punctured as in the above-described manner, but not freely incised, and after being thoroughly washed with carbolized water, two and a half per cent., the solution of chloride of zinc is injected, and dry charpie applied as before. The dressings are used three times a day.—*Revue de Thérap.*, January 15, 1884.

PARENCHYMATOUS INJECTION OF ERGOT IN SPLENIC ENLARGEMENT.—FENOGLIO recommends the injection of ergot in cases of splenic enlargement due to malaria. He recommends Bonjean's ergotin, dissolved in hot water, injected before the midday meal, while the stomach is empty.—*Centralbl. f. d. med. Wissensch.*, December 15, 1883.

SYPHILITIC FEVER.—DR. DUFLOCQ relates (*La France Méd.*, August 30, 1883) the history of a young man, twenty-five years of age, who was admitted to a hospital suffering from a fever. The attack had begun eight days previously with headache and vertigo followed by vomiting, after which fever and diarrhœa came on. There was also epistaxis a few days later. On admission the patient presented nearly all the symptoms of typhoid fever; the tongue was white; there was tenderness on pressure in the right iliac fossa, though the belly was not tympanitic; the spleen was slightly enlarged; heart and lungs were healthy. The temperature was 104.7°. The eruption of rose-colored lenticular spots was confluent over the abdomen, and very thick over the arms, legs, and thorax. They were large, slightly elevated, and disappeared momentarily on pressure. It was the great extent of this eruption that excited suspicion and led to further examination. A cicatrix resting upon an indurated base was found upon the glans penis, and there were enlarged glands in the groin. Mucous patches were discovered in the mouth and fauces. The patient was placed upon ordinary antisyphilitic remedies, and the fever and eruption disappeared in about two weeks. Dr. Duflocq mentions, as of diagnostic value in the differentiation of typhoid from syphilitic fever, the early appearance (third or fourth day) and the abundance of the eruption.—*Practitioner*, January, 1884.

SALICYL-RESORCIN-KETONE.—Salicyl-resorcin-ketone is a compound which is formed when salicylic acid and resorcin are heated together to 195° or 200° C., and, as might have been expected, it shares to some extent the antiseptic and antipyretic properties of the bodies from which it is prepared. According to HERR REPOND (*Zeitsch. der Allgem. öst. Apoth. Ver.*, xxi., 502), in small quantities it is less powerful as an antiseptic than either salicylic acid or carbolic acid, its action being to limit the development of, rather than to kill, the septic germs. It is, however, non-poisonous, repeated doses of two grains having been administered without inconvenience; it has been found useful for surgical dressings, and has been given to the extent of three or four grammes daily in typhoid fever without producing any unpleasant symptoms. Salicyl-resorcin-ketone is soluble in 1000 parts of water at 40° C., soluble with difficulty in hot water, and easily soluble in glycerine and alcohol. It melts at 133° to 134° C., gives when in solution a red-brown color with perchloride of iron, smells faintly aromatic, and has a not disagreeable taste. The corresponding compound with phenol, salicyl-phenol-ketone, is still less active as an antiseptic, and is more insoluble, but is said to be non-poisonous even in ten-grain doses.—*Lancet*, January 5, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 9, 1884.

THE MODERN OPERATION FOR THE RADICAL CURE OF HERNIA.

PROFESSOR CZERNY, of Heidelberg, in 1879, published an account of his method of effecting a so-called radical cure of hernia, which consists of exposure of the sac by a free incision under antiseptic precautions, of reducing the protruded parts, of isolating the sac from the surrounding structures, including its neck in a catgut ligature, and cutting away the remainder, of returning the stump into the abdomen, and, finally, of uniting the refreshened edges of the ring with the continued catgut suture. This procedure includes two distinct operations. Uniting the edges of the ring with silver sutures was first done by the elder Gross, as we learn from his *System of Surgery*, 5th ed., p. 579, in a case of large scrotal hernia at the Philadelphia Hospital, in 1861, with a successful issue. The other step, namely, ligation of the neck of the sac and extirpation of its fundus, originated, in 1876, with Riesel, who described it in the *Deutsche medicinische Wochenschrift*, Nos. 38 and 39, 1877.

Ligature of the neck of the sac, with excision of the fundus and stitching together the margins of the abdominal opening, appears to be freely and successfully practised by the surgeons of Liverpool. In the debate which followed the reading of a paper upon this subject at the Medical Institution of that city, by DR. HAMILTON, which may be found in the *Medical Times and Gazette*, for December 29, 1883, and the *Lancet*, for January 5, 1884, the fact was elicited that it had been done by Mr. Banks between fifty and sixty times, by Dr. Alexander thirty times, by Mr. Parker twenty-eight times, and by the Surgeons of the Northern Hospital fourteen times, and, strange to say, without a single death. As a rule, catgut was employed for the neck of the sac, and silver wire for the pillars of the ring.

This operation is applicable to all kinds of hernia, reducible or irreducible. According to Mr. Banks, it should not be performed in young children, unless the opening is very wide, or the child is unable or dislikes to wear a truss. In adults, it is especially useful when there is adherent omentum in the sac, and in hernia complicated with undescended testicle, conditions in which a truss is ineffectual. In cases of this description, the omentum or testicle should be removed. In ordinary examples of reducible hernia, it is contraindicated, unless life is rendered miserable by the disease, or the subject is rendered unfitted for work. The patient should remain in bed for at least three weeks after the operation, and wear a light truss afterwards for additional security; but in none of Mr. Parker's cases was a truss applied, and some of the subjects were up within a week, as he does not think that recurrence of the hernia is referable to the absence of such precautions.

The modern operation for rupture is one of expediency, not one of necessity. It may be resorted to directly for curative purposes, or as a part of the operation for strangulated hernia. Hence, in estimating its merits as to safety, the former class of cases can alone be taken into account, as it in nowise increases the dangers of the latter class; while both groups should be considered in arriving at a conclusion in regard to its curative effects.

The mortality of the Liverpool cases, which number about one hundred and twenty-five, was absolutely nothing, a fact which reflects great credit upon the surgeons of that city. Unfortunately, little is said of recurrence of the trouble. Of twelve cases in the Northern Hospital which had been observed for at least six months, ten were cured and two failed. The results of twenty-one operations in the hands of Mr. Banks, in which a sufficient time had elapsed to apply the test, and recorded in the *British Medical Journal*, for November 18, 1882, indicate fifteen complete cures, four partial successes, and two failures. Hence, 24.2 per cent. of these thirty-three cases failed.

In a monograph, entitled *Die Moderne Radikaloperation der Unterleibsbrüche*, Hamburg, 1883, DR. LEISRINK has collated 390 cases, which throw the desired light upon the questions of mortality and efficiency. Of 202 curative operations, that is to say, performed upon reducible herniæ, 187 recovered, and 15 died; of the former, 20$\frac{1}{9}$ per cent. recurred. Of 188 operations in connection with strangulated hernia, 155 recovered, and 33 died, but nothing is said of relapses.

The combined results of the Liverpool cases, and of those collated by Leisrink, show that of 515 operations for reducible and strangulated herniæ only 9.3 per cent. died, of which about 2 per cent. may be ascribed to the strangulation itself, since the mortality of the operation for reducible hernia, as shown by Leisrink, is 7.4 per cent.

The natural conclusions at which we would arrive from a consideration of the foregoing facts are, first, that, although the modern operation kills about one patient in every thirteen or fourteen, and fails in about one case in every five in which it is resorted to as a matter of expediency, it none the less is of great value in restoring many persons to comfort and the possibility of earning their living; and, secondly, that it should be practised in all operations for strangulated hernia in which the gut can be returned into the abdomen.

In a paper contributed to the *Nordiskt Medicinskt Arkiv*, vol. 25, part 4, Lindfors, of Lund, records two examples of the radical cure of congenital omphalocele, the operations having been performed by himself and Krukenberg. The sac, having been previously incised if adhesions are present, is cut away, and the refreshened edges of the opening are united by sutures. In both cases the recovery was complete in four weeks. Instances of a somewhat similar nature have been reported by Rosander, in *Schmidt's Jahrbücher* for 1878, and Banks, in the *British Medical Journal* for November 18, 1882. In both, the sac and a portion of the omentum were removed, but the ring was not sutured. In none of the four had sufficient time elapsed to form a conclusion as to a final cure.

A NATIONAL PHARMACOPŒIA.

On another page we give, from the *Journal of the American Medical Association*, the text of a bill to establish a national pharmacopœia, which has been recently introduced in the House of Representatives and referred to the Committee of Ways and Means. Our readers can thus consider its provisions for themselves, and form an intelligent opinion as to the method proposed for carrying out the object of the bill. That object, we believe, will meet with virtually unanimous approval on the part of both the medical and pharmaceutical professions, as it will simply place the United States on a level in this respect with other civilized nations. From the report of Dr. Flint, U.S.N., to the Smithsonian Institution, we learn that "of nineteen pharmacopœias in use in different countries of the world, fifteen were issued under government authority, and their directions have the force of law in their respective countries. The other four, viz., United States, Mexico, Switzerland, and Tessin, were prepared by commissions appointed by medical or pharmaceutical societies, and have no other authority in their support than that of the societies from which they emanate." Professional men in general, we suspect, will agree that we have followed the Mexican system long enough.

That the want of such a national and authoritative standard has not hitherto been pressingly felt is owing to the fact that for fifty years—from 1830 to 1880—the necessity was met by the voluntary action of representative members of the two professions, actuated only by professional and scientific zeal, and the result of their labors was freely given to their fellow-members at the lowest price compatible with accurate execution. Unfortunately, since 1880 the *United States Pharmacopœia* has become a matter of commercial speculation. While a vast amount of intelligent and well-directed labor was bestowed upon it by members of the Committee of Revision, taken as a whole it is by no means creditable to the science of the country, and complaints as to its inaccuracy and the inconvenience of its methods have been numerous. Not only was it thus inferior to former revisions, but it was padded out into an absurdly large and clumsy volume, and supplied to the profession at an extravagant price, wholly disproportionate to its former rate. That this departure from the time-honored course followed in former revisions should awaken widespread dissatisfaction was inevitable; and it was to be anticipated that that dissatisfaction would lead the Government to supply a want which had always existed, but which had never before become so imperative as it is now.

Congress, of course, has no power to establish by law a standard for the manufacture and dispensing of pharmaceutical preparations, and we see that the proposed Bill makes no attempt to do so. The government, however, has the power, and it is its duty, to furnish an authoritative standard for the use of its own officers in the military, naval, and marine-hospital services; and the Treasury Department, moreover, has long felt the need of some legal standard whereby to construe the tariff on drugs. It is primarily to meet these necessities that the proposed legislation is sought, and if, as is probable, the practitioners and pharmacists throughout the country adopt the same standard, we shall have what we have hitherto lacked, a pharmacopœia national and authoritative, in fact as well as in name. We observe that the Bill invites the coöperation of the Medical and Pharmaceutical Associations, which will doubtless be freely given, and the result of the combined labors of the ablest men in their respective branches, working under the auspices of the government, can hardly fail to be eminently credit-

able to the country at large and to give a fresh stimulus to pharmaceutical science.

As we have said above, we have no doubt that the plan for accomplishing so worthy an object will meet with a professional approval practically unanimous. It was to be expected, of course, that the commercial interests represented in the present *Pharmacopœia* as a business enterprise would object to a competition which threatens to be overwhelming, but this antagonism will be rated at its true value. The professions at large, who have been forced to purchase at a high price a work which is imperfect in many respects, will be gratified to obtain, at a minimum cost, a standard authority on which they can implicitly rely, if the work be executed as perfectly as there is every reason to expect.

While the decision rests with Congress, the question is one which ought to be settled by the weight of professional opinion. We therefore trust that all intelligent physicians and pharmaceutists will give this matter the reflection which its importance demands, and will communicate their views, whether favorable or adverse, to their members of Congress. We frankly believe that the measure must inevitably pass on its merits at this session, if it is not crowded out by the bustling legislation of a presidential year. We likewise believe it to be inevitable that if it fails at present, it will be again brought forward, and that its final success is only a question of time.

INTERNAL ŒSOPHAGOTOMY FOR CICATRICIAL STRICTURE.

In the current issue of The Medical News, Dr. Sands, in a highly practical, valuable, and exhaustive paper, calls attention to the merits of internal incision in the treatment of cicatricial stricture of the œsophagus. His case was that of a child eight years of age, who was at death's door from an obstruction, due to swallowing a solution of caustic potassa, situated eight inches and a half from the incisor teeth. After attempts to introduce an instrument for six days, a filiform whalebone bougie was finally passed, after which dilatation was practised almost daily for five months, or until it was possible to insert an elastic bougie, No. 17, French scale. During the succeeding three months and a half, the band was divided not less than seven times with an instrument devised by Dr. Sands, and five weeks later the patient was discharged, having increased her weight by one-half, and dilatation to 39 of the French scale having been accomplished. At the date of the last report, or three months after the last incision, there was no tendency to recontraction.

In the case thus briefly outlined, the subject was restored to comparative comfort and health, although too little time has elapsed to base a conclusion as to a permanent cure. The subsequent history of such cases, however, indicates that, almost without exception, recontraction ensues, particularly in children, who are difficult to manage. Hence, we regret that Dr. Sands did not base his estimate of the comparative value of the different operations for cicatricial obstruction of the gullet upon statistics derived from cases of children alone, as they constitute a class of subjects very distinct from adults in regard to the prognosis after interference.

Omitting the case of Boeckel, cured by electrolysis, we happen to have before us the details of nineteen operations for cicatricial stricture in children — several derived from private sources — which will throw some light upon their relative merits. Of four œsophagostomies, all died; of three internal œsophagotomies, two were living, respectively, at the end of five months and three months, the cases being those of Roe and Sands, while one, that of Czerny, died from complete division of the tube. The single case of combined œsophagotomy of Gussenbauer was alive at the end of one year. Of eleven gastrostomies, four died, the mortality percentage being only slightly greater than that of internal œsophagotomy. The four internal œsophagotomies, including the combined operation of Gussenbauer, indicate an average prolongation of life of one hundred and fifty-five days, three patients being alive at the expiration, respectively, of three, five, and twelve months. The eleven gastrostomies, on the other hand, show an average life of three hundred and sixty-nine days, Staton's being alive at the end of five months, Albert's at the expiration of five months and a half, and Herff's, of San Antonio, Texas, at the end of four years and five months. More than this, Trendelenburg's patient died in four years from abscess of the brain, the result of caries of the petrous bone following scarlet fever. The remaining cases survived two, seven, and eight months.

These results speak strongly in advocacy of the more simple operation of gastrostomy for cicatricial obstruction of the œsophagus in children, and their consideration leads us to regard it with more favor than does Dr. Sands in the paper referred to.

BACILLI IN THE MILK OF ANIMALS SUFFERING FROM SPLENIC FEVER.

Reich has recorded some observations which show that phthisis was transmitted by a phthisical nurse to a number of children, and Epstein believes that the disease may be transmitted to infants by the ingestion of the milk of tuberculous cows. There is, moreover, abundant evidence to prove that milk is capable of distributing enteric fever, diphtheria, smallpox, and scarlet fever, and it is probable that

it will be found to be one of the agents of communication of other diseases.

Splenic fever, anthrax, or charbon, as the affection is variously termed, is known to be very common among our domestic animals, and the blood contains enormous numbers of bacilli. Straus and Chamberland have demonstrated the fact that, through artificial inoculation, these organisms pass into the blood of the fœtus, the bile, and the urine; and in a recent communication to the Faculté des Sciences de Bordeaux, which may be found in the *Gazette Hebdomadaire*, for November 30, CHAMBRELENT and MOUSSONS have demonstrated in sucking guinea-pigs the passage of bacilli anthracis into the milk, in which fluid, however, they are far less abundant than in the blood. If future observations should show that the milk of cows suffering from splenic fever constitutes a favorable nidus for the growth and dissemination of these organisms, the application of the knowledge will be obvious.

CALCIC NEPHRITIS.

IN our issue of last week we called attention to the uric acid, or gouty, nephritis, and in this connection it behooves us not to lose sight of the fact that there is also a calcic nephritis, caused by deposits of lime in the uriniferous tubules. Unlike the uric acid deposits which are found in the straight tubes of the medulla, these are very often found in the cortex of the kidney, especially in the capsules of the glomeruli, where sometimes they form concretions of such size that they are visible to the naked eye. But they also occur in the convoluted tubes of the cortex, and even in the straight tubes of the medulla.

The chronic interstitial nephritis which attends these calcic deposits is, in many respects, similar to that associated with gouty nephritis. Indeed, it is mainly distinguished from this form by the tendency it exhibits to produce small cysts, which originate in constrictions of the uriniferous tubules. The tubules, including the straight tubes, form, first, varicose loops and tortuosities, which are gradually cut off from the tubule itself. Thus originate a series of cysts, which enlarge, and by their confluence form larger sacs.

Virchow has also described a series of cases in which these limey deposits in the tubules of the kidney appear to be metastatic, that is, large quantities of calcareous matter are dissolved out in certain diseased states of the bones and carried into the circulation, whence, among other situations, they are deposited in the kidney.

Still another mode in which lime salts occur in the kidney, is in the shape of an infiltration of the basement membrane of tubes bereft of epithelium. These, beginning on the apices of the papillæ, radiate thence in white lines towards the bases of the cones. On section, the tube is patulous, without epithelium, its walls being simply infiltrated with the lime salts. The cause of this condition would appear to be a catarrhal process resulting in a desquamation of the epithelium, with a subsequent calcareous infiltration, against which the epithelium had previously apparently protected them.

QUININE PILLS, AGAIN.

WE had felicitated ourselves that the exposure in THE NEWS, a year ago, of the prevalent shortage in the quinine pills of leading manufacturers, had led to greater accuracy in the compounding of these important little articles. That it did so, at least for a time, we have no doubt; but the permanence of the improvement is gravely questioned in a statement made by Messrs. McKesson & Robbins in the *Druggists' Circular* for the current month. That well-known firm asserts that it has analyzed samples of various brands of quinine pills, with the result of finding shortages running all the way from seven to thirty-five and a half per cent. of the alkaloid. Unfortunately, it does not mention the names of the makers of these short-weight pills; but it threatens to do so unless they speedily reform. We welcome all allies in the good cause, and shall watch with interest the result of this new investigation.

Messrs. McKesson & Robbins further promise next month to furnish a new and simple process for the assay of quinine pills with reasonable accuracy, enabling every competent pharmacist to determine for himself the value of what he dispenses. As all the processes heretofore relied upon are somewhat complicated and troublesome, we shall be very glad to see the new method, and to test its practicability.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THIS year's meeting of the Medical Society of the State of New York retained the New Code as its point of pivotal interest. Although an unofficial, yet probably accurate, canvass of the five thousand physicians in the State had shown a clear majority to be opposed to the New Code, and a minority of but one-fifth in its favor, yet it was regarded as a foregone conclusion that this minority would be so interested in its maintenance as to insure their presence at the meeting in sufficient number to give them a majority. Hence, the result of the vote on Dr. Didama's resolution for the restoration of the National Code was not unexpected.

As the outcome of this action, the adherents of the National Code felt impelled to uphold what they consider the right. They, therefore, held a meeting on Wednesday morning and organized a new State Society.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-eighth Annual Meeting, held in Albany, February 5, 6, and 7, 1884.

(By Telegraph from our Special Reporter.)

TUESDAY, FEBRUARY 5TH, FIRST DAY.
MORNING SESSION.

THE Society met in the Geological and Agricultural Hall, and was called to order by THE PRESIDENT, ALEXANDER HUTCHINS, M.D., of Brooklyn, and the meeting was opened with prayer by the Rev. Dr. King, of the Emmanuel Baptist Church.

THE PRESIDENT, ALEXANDER HUTCHINS, M.D., of Brooklyn, then delivered the

INAUGURAL ADDRESS,

of which the following is an abstract:

Gentlemen: In the name of the Medical Society of the State of New York, venerable through its seventy-eight years of active history; with a constituency so large, so preëminent, and so productive; with a cultured enthusiasm that has neither waned nor faltered; with a series of acquisitions, each, in its turn, abreast of the advancing triumphs of medical learning, I am privileged to welcome you to this meeting.

I submit to the Society whether some change in its business detail cannot, profitably, be made in the interest of its scientific work. The Society meets so rarely that it would not be desirable to abridge, in any way, the open discussion of all matters pertaining to its routine and legislative functions; but the remaining hours of its session could be more satisfactorily filled if it should be so desired. There are various methods of accomplishing this, but I prefer to propose that the Society, by special resolution, instruct or permit my successor to appoint the Business Committee in advance of the meeting, that they, in connection with him, may arrange for the presentation of the scientific work at the next meeting on some more or less flexible plan, and the Society can thus, perhaps, better judge if it is wise to formulate this provision in a by-law. I suggest that an effort might be made to call out original work by announcing at each meeting a number of *queries*, to which answers are solicited at the next succeeding meeting. Another suggestion is to devote one session to what is known as the "Omnibus Meeting," where, in an informal and volunteer way, individual experiences are offered in large numbers and rapidly discussed. This is essentially free-lance, social, and instructive.

I place before you certain documents relating to the Bill (H. R. 48) providing for the erection of a building to contain the records of the library and museum of the Medical Department, U. S. Army, introduced December 10, 1883, and referred to the Committee on Public Buildings and Grounds, and I advise the formation of a committee to memorialize Congress on behalf of that measure.

I call your attention to the subject of hospital-trained nurses, and advise a convention of representatives of the several schools to effect uniformity of curriculum, adequacy of instruction, and the assured qualifications at graduation.

I beg to suggest that this Society can, with great propriety, further the interests of the *Index Medicus*, by an appropriation of money to secure the continuance of that important publication.

The subject of medical education has commanded the attention of this Society. Certainly no more important matter can occupy its deliberations, and yet this Society has no authority over the medical colleges. The preliminary education of medical students has been under discussion in this Society and elsewhere, and the matter of a better preliminary education has been advised and endorsed by this Society, but nothing has been accomplished. In the opinion of the speaker the whole discussion is fruitless, and must be so, under the existing management of medical education.

The authority to license granted to the incorporated societies and the degrees conferred by colleges have had the common sequence of right to practise—latterly, after compliance with certain formalities. The power of conferring a degree and the license to practise are, certainly, different things, and it is proposed to enunciate and legalize this difference. The object of obtaining the degree is to give the right to practise, and the preliminary acquisition of the degree is to be the acquisition of an empty honor till it has been endowed by the State, after compliance with certain conditions, which are, practically, a repetition of the conditions in accordance with which the degree was given. This after-criticism of the colleges, the extra machinery, and the increased expense are offered as safeguards to the community.

Granting the ideal wisdom of the scheme, there are many vested rights that must be consulted, many conflicting interests to be harmonized, and a gathering-in of advice from the large experience of medical men throughout the State, before this Society even would be competent to give voice to any resolution looking to the enforcement of so radical and far-reaching legislation. As in all other matters, so in this, this Society can act wisely only as it reflects in its actions the sentiments of the various bodies it represents; and it is competent for this Society to initiate action that shall discover the conclusion in this matter at which the medical practitioners in the State have arrived. These criticisms are made in full knowledge of the fact that the Erie County Medical Society has given large consideration to the production of a bill looking to a radical change in the licensing authorities. The Erie County Medical Society consulted with the Committee on Legislation of this Society and had its hearty approval of the measure; and, later, this committee assumed its responsibility. In a sense, therefore, this bill has the endorsement of this Society, and the Society will listen with curiosity and interest to the explanation its committee may give as to the expected workings of this measure; still, as it is so much easier to avoid hasty legislation than to secure its repeal, the Society is entitled to exhaustive information before giving its approval to this or any other measure.

Another bill, of similar intent, but varying in detail, is before the Legislature. They both, however, have

the common provision of a mixed board of examiners appointed by the State. I have no information whether the two chartered bodies of special practice have been consulted in the preparation of these bills, or whether it is proposed to legislate them into competency of representation in this licensing board, leaving them free to accept the representation or not, as they may elect. Personally I have no faith in any ultimate good to result from this kind of legislation, beyond additional police regulation of compliance with form. I see ground for opposition to it, in the way of preventing possible unlimited political combination and chicane. It is well to recollect the conceded fact that, in skilled and accomplished teachers, and in completeness of equipment in all the multiform appliances for medical instruction, this country furnishes opportunities surpassed by none. The deficiency is not here. That legislation will be consummate which shall formulate the wise experience of the best into a curriculum, the fulfilment of whose probation shall be an adequate assurance that the requisite time and opportunity have been given for the novitiate to have become the student, and the student to have acquired the scholarly habits competent for the mastery of his profession. It is at the end of the line that the real reformation is to begin. Within this Society rests the experience competent to prepare that curriculum. Holding, as I do, the supremacy of this Society as the natural guardian of medical interests in the State, I would legislate this Society into closer relations with the medical colleges, rather than subject the colleges to the unstable condition of political appointees.

Three separate proposals affecting the question of the Code were made at the last meeting, to be called up at the present session—one by Dr. Didama, of Syracuse, another by Dr. Roosa, of New York, and a third by Dr. Howe, of Buffalo. These proposals present three distinct phases of the question, and will be at the disposition of the Society.

The practice of medicine is so beset by parties and factions, that the dissension and sorrow that have occurred in our own ranks are greatly to be deplored. That men, who have commanded respect not only in their own communities, but for years in this body, should feel bitterly, over the action taken by it, is a matter of profound regret. It would appear that the question of the Codes has gone beyond the discussion of the principles involved in the main issue, and has advanced to the stage when this Society is simply to decide whether it proposes to adhere to its policy of the past two years, or reverse it. The sentiment of the profession in the State on the main issue is better known to-day than at any period since the original action, two years ago. The results of a canvass of the physicians in affiliation with this body have been published, and, if not authoritative, they are so detailed as to admit of immediate contradiction, if incorrect. By the exhibit it appears that of the five thousand physicians canvassed, a majority are opposed to the present policy of the Society, while a minority of about one-fifth openly favor that policy. As the action of this Society is binding on the County Societies, and the aggrieved members of the County Societies must find their redress through *this* Society, if at all, the issues seem very clearly defined, provided the accuracy of these figures can be supported. They who hold the autonomy of this Society, its independence of professional sentiment, and the moral right to legislate in opposition to the major professional sentiment, can properly sustain its present policy; while they who hold that this Society is essentially a representative body, under moral obligation to legislate in accord with the major professional sentiment, are logically bound to oppose the present policy of this Society. I hold that opinion on these issues is one strictly of justice, and entirely apart from prejudice in favor of either of the Codes. On an issue which profoundly affects professional tradition and personal conviction of right and duty, this Society has adopted and confirmed a policy. On the wisdom of that policy the Society itself is very evenly balanced. The action of the Society forced each of its constituents into an attitude, hostile to his past relations with his professional brethren and the community, on a question where principle was involved. No effort was taken, at the time, to ascertain the major professional sentiment, and the Society has taken no measures since to discover opinion on its policy. The majority of the constituents of this Society are in sympathy with its policy, or they are opposed to it. If the majority of the profession in the State are in accord with the action of the Society, no injustice has been done. If the majority are opposed to its action, the Society should decide whether justice and fair-dealing require it to reverse its action to conform to the convictions of that majority.

Conscious that in this prolonged discussion, I have laid myself open to the criticism of undue (and therefore needless) intrusion of personal opinion, I still have the absorbing desire and the strong hope that your deliberations may be so temperate and well informed, as to lead to the settlement of policy so wise, that opposing sentiment may suffer the least possible shock, and the forces that underlie all professional activity be girded with renewed vigor in their efforts to support the dignity and usefulness of the profession.

The President then appointed the following

COMMITTEES.

Business Committee.—Drs. J. W. Moore, of Albany Co.; A. M. Phelps, of Franklin Co.; and J. H. Hunt, of Kings Co.

Committee on Credentials.—Drs. I. N. Goff, of Madison Co.; James Chapman, of Orleans Co.; P. R. H. Sawyer, of Westchester Co.

After a recess of ten minutes,

COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES

were called for.

The Medical Society of the County of Albany, presented the following: At a regular meeting of the Medical Society of the County of Albany, held on February 1, 1884, the following recommendation of the Committee on Legislation was adopted: "Although containing defects the Bill presented by the Committee on Legislation of the Medical Society of the State of New York seems, if properly enforced, to be able to accomplish the purpose designed; we therefore recommend that the Medical Society of the County of Albany lend its influence to the endeavor which is being made to make the provisions of this Bill the law of the State."

On motion, the subject of this communication was

made the special order of business for Wednesday morning.

The Medical Society of the County of New York presented certain suggestions with reference to the by-laws, which were referred to the Committee on Business.

THE CODE OF ETHICS.

The Ontario County Medical Society presented the following resolution, which it had passed:

Whereas, Our State Society by a majority vote confirmed the amendment to the Code of Medical Ethics, adopted the year before, called the New Code; and,

Whereas, The New Code, so adopted, is antagonistic to the National Code of Ethics; and,

Whereas, The American Medical Association refuses to affiliate with, or to admit delegates or members from, any society or association which does not adopt or endorse the National Code of Ethics, therefore

Resolved, That this Society places upon its records the reiteration of its adherence to the Code of National Ethics, as adopted by the American Medical Association.

Resolved, That it is the earnest request of a large majority of the members of this Society, that our delegates to the State Society use every endeavor and all honorable means to so modify or alter the New Code of Ethics that it may be in harmony with the National Code of Ethics.

Resolved, That our Society be requested to transmit a copy of these resolutions, together with the number of votes, both yea and nay, to the Secretary of the State Medical Society, which were carried by a vote of seventeen yeas to four nays.

The Medical Society of the County of Washington presented the following resolutions, which it had adopted:

Resolved, That it is the sentiment of this Society that it is the bounden duty of the Medical Society of the State of New York to so modify its present Code of Ethics as to be entitled (as formerly) to representation in the American Medical Association, and thus, by its delegates and representatives in that honorable body, have the right of protest and of effort to secure immediate reform in a legitimate manner.

Resolved, That it is the sentiment and earnest request of this Society that the American Medical Association, without unnecessary delay, do modify, change, and adapt its Code or System of Medical Ethics, so as to meet the wants and demands of the medical profession of the present day and generation.

Resolved, That our Society be requested to forward a copy of the foregoing resolutions to the Secretary of the State Society and of the American Medical Association.

DR. A. JACOBI, of New York, offered a resolution calling the attention of Congress to the importance of the speedy passage of the bill providing for the erection of a

FIRE-PROOF BUILDING FOR THE MEDICAL DEPARTMENT OF THE ARMY.

The resolution was adopted, and it was ordered that it should be sent to the proper committee, attested by the seal of the Society and the signatures of the President and Secretary.

DR. J. P. CREVELING, of Auburn, reported a case of

DOUBLE HARELIP.

A young girl, æt. 11, was born with double harelip. The entire intermaxillary bone was adherent to the septum of the nose, and protruded some distance in advance of that organ, and rendered nursing very difficult. In order to diminish this difficulty, the projection, which was covered with mucous membrane, was removed, except a small part at the distal extremity. The case was then lost sight of until November, 1883, when she was admitted to the City Hospital for operation. The fissure began at the ala nasi on either side, and extended backward and downward to the angle of the mouth. Both intermaxillaries were gone. The operation consisted in free dissection of the cheeks, from the bony surfaces throughout their whole extent. The alæ of the nose were also divided. The incision on the right side began at the ala of the nose, and extended to the angle of the mouth, through two-thirds or more of the lip; on the left side a corresponding incision was made, except that the whole thickness of the lip was cut through. These flaps were transfixed at their central part, and a large pin was passed near the bottom of the first incision. The right and left flaps were then brought into apposition and firmly held by a pin. Another pin was introduced at the mucous margin of the lip, and two small pins at intermediate points, and the whole was secured by proper bandage. The advantages claimed for this operation are that the extent of adherent surface is one-third greater than that obtained by the more central incision of the lip, and that it also prevents the secretions of the mouth from finding their way between the edges of the wound. In the case reported union was perfect.

DR. W. C. WEY, of Elmira, moved that a committee of three be appointed, to which the President's Address be referred.

DR. WEY then reported *Two Unusual Cases in Obstetrical Practice.*

DR. DAVID LITTLE, of Rochester, then read a paper on

SUMMER COMPLAINTS IN CHILDREN.

After referring to the subject of diet, he related his experience in the Rochester Orphan Asylum, where, up to 1882, there had always been a number of cases of this disease each summer. At this time he instructed the nurse to feed the children every three hours, and to give them as much water as they would take. The summer passed without a single case of diarrhœa. In the summer of 1883, the same plan was adopted, with the same result. Only two cases of diarrhœa occurred, and they were in children of tuberculous parents, who had exhibited scrofulous manifestations.

DR. WOOLLEY, of New York, thought that, in considering the efficacy of any special plan of treatment, it was necessary to remember the effect of epidemic influence, which, since 1882, had not been very marked.

DR. W. S. ELY, of Rochester, thought that more was to be gained from the regulation of diet than from medicines. A few weeks ago he had seen a case in which this point was clearly illustrated. The child was five weeks old, and had from eight to ten stools per diem; on inquiry he learned that the child took about four

pounds of food per day, and that it had taken large quantities of medicine. On this diet it was losing about one-quarter of a pound per week. Recovery followed suspension of all remedies, regulation of diet, and the free use of water and warm baths.

THE COMMITTEE ON PRIZE ESSAYS

reported that there had been two essays submitted: (1) on *Tuberculosis of the Breast*, by Dr. Ghislani Durant, of New York, for which the Cash Prize was awarded; (2) on *Consumption*, which was thought worthy of publication.

DR. A. G. GERSTER, of New York, then read a paper on

CANALIZATION AS APPLIED TO AMPUTATION OF THE FEMALE BREAST TO INSURE PRIMARY UNION UNDER ONE DRESSING.

Canalization was first introduced by Neuber, of Kiel. It is a process by which good drainage is afforded to a wound without the use of drainage-tubes. There are two kinds, shallow and deep canalization.

The first is employed for draining extensive subcutaneous cavities, situated beneath large skin flaps. It is accomplished by the aid of a punch, devised by Neuber, similar to the common leather punch, the hole which it makes being elliptical. Any subcutaneous fat which protrudes through the opening made by the punch is to be removed with scissors. As many holes as will suffice to carry away the secretion are made through the dependent portion of the wound. If the wound is extensive, it is well to scatter a number of holes over the entire flap covering the wound. Deep canalization is used to afford drainage to secretive accumulations in the recesses of deep wounds. Here intermuscular planes are opened up, and the dangers of retention and suppuration are more grave than in the case of shallow wounds. These cases will often require the use of a drainage-tube.

The invention of absorbable drainage-tubes by Neuber, is an important step forward. These tubes are made of ox bone, and when decalcined and disinfected, behave in a wound exactly like catgut. Even this is a necessary evil, and Neuber advises a procedure which will do away with the necessity for drainage-tubes. He advises that the skin on both sides of a deep wound be detached so as to make it movable, then turn it into the bottom of the cavity and fasten with catgut sutures. In this way the greatest portion of the cavity becomes lined with skin, and it can heal by adhesion, and the funnel of cutis serving at the same time as an unobstructible channel for draining the bottom of the cavity. This is *deep canalization*.

The author then referred to the result obtained by Esmarch in the use of absorbable drainage-tubes in amputation of the female breast. Over forty cases were treated in this way, healing throughout by first intention.

In this operation, it is important to remove the axillary glands, which causes a large cavity, where, if suppuration be not avoided, a large amount of cicatricial tissue will be produced, which, from its close relation to the vein and brachial plexus, is apt to cause œdema and pains radiating down the arm. In order to avoid this disadvantage, and to do away with the necessity for use of absorbable drainage-tubes, which are difficult to procure, it was thought proper to try Neuber's idea of deep canalization, as adapted to the axillary cavity.

The following case, illustrating this method of treatment, was reported:

Miss C. H., somewhat anæmic. One year before, she had noticed an irregular nodosity in the left breast. Amputation of the breast and evacuation of the contents of the axillary cavity were performed November 30, 1883. Solution of corrosive sublimate (1 to 1000) was used for irrigation, and four holes were punched into the skin of both sides of the wound. The anterior portion of the wound was united with two continuous catgut sutures. The edges of the axillary portion of the wound were dissected up for about an inch on both sides; then the anterior skin-flap was transfixed with a stout catgut suture, and being turned well into the apex of the armpit, was sewed to the posterior aspect of the pectoralis minor muscle. The posterior flap was sutured to the latissimus dorsi. In this way the axillary cavity is transformed into a cone, lined with skin, at the apex of which, a small portion of the deepest part of the axilla remains uncovered. After this, a strip of gauze, dusted with iodoform, was laid on the line of sutures, and a large pad of sublimated gauze was snugly bandaged on to the shoulder and thorax.

On the eighth day patient left the bed. Two weeks after operation the first dressing was removed, and the entire wound was found healed by first intention in the literal sense of the term.

On microscopical examination. the tumor was found to be an adeno-sarcoma, containing a large number of miliary cysts.

Two more cases were reported, in which the same results were obtained by this plan of treatment.

The paper closed by saying:

The limited experience gathered in the foregoing cases seems to justify the assumption that, when Neuber's bone drainage-tubes cannot be procured, primary union of the entire wound in a normal amputation of the female breast can, by the employment of deep canalization, nevertheless be attempted and accomplished under one dressing.

DR. OREN D. POMEROY, of New York, then read a paper on

MALFORMATIONS OF THE AURICLE,

relating a case on which he had operated. The latter was as follows: E. F. W., Jr., æt. 16, had a malformation of the left auricle which was congenital. The meatus with the auricle was placed nearly three-fourths of an inch lower than its fellow. The upper portion of the auricle was attached to the cheek, in front of the meatus, somewhat covering the latter, and interfering with perfect audition.

The peculiar, doubled-up appearance of the ear gave it the characteristics of what is known as cat's ear, and was very unsightly. No hereditary cause for the trouble could be found. Two operations had previously been performed by a surgeon of Boston, Mass., which had rendered the deformity worse rather than better. One or two very small portions of rudimentary auricle had been removed, however, at that time, which improved the patient's appearance. The side of the face, the fauces, the chest, and, indeed, most of the left side of

the body, showed signs of arrested development. A mitral regurgitant murmur was present, and the patient was not very strongly developed. Ether was administered in the operation, although a full effect was avoided on account of the weakly condition of the patient, including the heart trouble. The auricle, at its faulty attachment, was divided on a level with the surface of the face, far enough back to allow it to be drawn up into a normal position. An incision above, and somewhat in front, of the mastoid region, was made through the skin; this being somewhat undermined, permitted a sufficiently uncovered surface to appear, to which the auricle was attached by sutures, of which twenty were used. Most of these were inserted into skin, but about three or four were needed to transfix cartilage. The wound made by dividing the auricle was closed by undermining the skin and using sutures. The healing was prompt and satisfactory. The sutures inserted into the cartilage caused some irritation, while those in the skin caused none. Dr. Pomeroy quoted cases where sutures were passed into the cartilage of the auricle, without causing undue irritation, and a case where a severe wound of the cartilage of the meatus and auricle healed promptly. He quoted most of the cases of malformed auricle found in literature, with a detailed description of the mode in which this arrest of development was brought about.

Dr. Mattison, of Brooklyn, said that, in a child ten years of age coming under his observation, and presenting a deformity similar to the one described, the auricle was separated from its attachments, its posterior surface and the skin covering the mastoid process were freshened, and perfect union ensued.

Dr. Jacobi, of New York, asked what was the experience of specialists in regard to the occurrence of this anomaly; whether it was usually accompanied by anomalies in other parts of the body?

Dr. Pomeroy stated that he had found, in at least half the cases, that the arrest of development involved no other organ but the ear, and that the arrest of development in other parts seems to bear no relation to the arrest of development of the ear.

Dr. George B. Fowler, of New York, then read a paper entitled

POISONING BY POTASSIUM CHLORATE.

A brief history of the drug was given, and reference made to its early popularity, which was based upon its oxygenating powers; this property being due to the fact that potassium chlorate ($KClO_3$), under favorable circumstances, readily gives up all its oxygen.

About the end of the eighteenth century this salt enjoyed a very limited popularity, but, during its previous fashionable period, Dr. Ferria, of England, had recorded its success in the sore gums of scurvy, and today its use is practically limited to diseases of the mucous membranes.

The accounts given of the effects of both large and small doses are conflicting, and the general opinion seems to prevail that chlorate of potassium is one of the most harmless of substances. The object of this paper is to prove and emphasize the contrary, and to show the real cause of death as proved by experiments on animals.

From time to time cases are reported where, on account of the unscientific manner in which the medicine is prescribed, death has resulted from its careless employment. Dr. Jacobi, in 1860, warned us against its lavish use, and recounted the feelings he himself experienced after taking ʒiv and ʒvi doses, they being "a sensation of heaviness and dragging in the lumbar region, and increase of the renal secretion."

In the 1868 edition of Stillé's *Materia Medica*, the author says, "There are only two examples of injury produced by chlorate of potash. The one occurred in a case of phthisis, for which a physician prescribed three hundred grains of the salt, to be taken daily, in solution. This unfortunate victim of professional ignorance took this dose on four consecutive days, when the pains in his bowels became very severe, incessant vomiting came on, and finally death ensued. The stomach was inflamed on its external surface, while its mucous coat was entirely disorganized and softened."

Dr. Fowler then referred to the well-known case of Dr. Fountain, of Davenport, Iowa, who, with experimental intent, took an ounce of potassium chlorate in a goblet of warm water; vomiting and diarrhœa ensued during the day. On the following day there were very alarming symptoms of collapse, and intense pain. Two ounces of black urine were voided, after which there was no renal secretion at all. He finally died one week after taking the dose, his sufferings having continued without intermission.

Larger doses have been taken without fatal results, and the variation in the quantity which has caused either death or alarming symptoms is very great, and rather peculiar. The possibility of an injurious effect appears to depend upon idiosyncrasy, condition of the stomach as regards contents, and whether the salt is in perfect solution. If it is not in solution, gastric symptoms arise.

About thirty cases are now on record where the cause of death has been attributed to an overdose of potassium chlorate, and the author holds, with Dr. Jacobi, that in many instances where the fatal termination of a case has been assigned to nephritis as a complication of the primary disease (diphtheria), that the rea cause of death was chlorate of potash.

In December, 1882, Dr. Fowler received a specimen of urine from a physician, accompanied by the information that it had been voided by a girl of fourteen, whose mother, having misconstrued the directions, had allowed the child to take ʒj and ʒij (six hundred grains) during one day. The patient became unconscious and cyanotic in the evening of the same day, and died two days afterwards, having remained blue and there being almost total suppression of urine. The specimen of urine was very interesting. Its specific gravity was 1055; it was of a very dark, bloody color, and was opaque. The microscope showed blood-corpuscles, crenated and dark brown. They were gathered in little masses throughout the field, and appeared agglutinated. It was evident that we had here urine mixed with a decomposition product of hæmoglobin, and placed before the spectroscope the characteristic spectrum of methæmoglobin was seen. Methæmoglobin is a substance found in old extravasations, hydrocele, and ovarian fluids, and can be prepared by the addition of dilute acids to blood coloring-matter. Spectroscopically, it is distinguished by an absorption band in the orange at C, the two characteristic bands of oxyhæmoglobin also persisting. Here

was a point. The blood color, the oxygen-carrier, had been destroyed. Was it effected by the potassium chlorate, or by mixture with the acid urine? Proceeding to experiment, it was found that warm, normally acid urine did not produce this decomposition; nor did even an excess of potassium chlorate in the cold; but, on warming the solution, the whole turned black, and under the microscope and before the spectroscope I found the same conditions as in the urine from the girl.

Methæmoglobin is incapable of supporting life, it cannot take up and deliver oxygen, hence the cyanosis observed in all these cases, and hence death ensues from asphyxia.

A saturated warm solution (about two ounces) was next injected into the stomach of a rabbit. After two hours the animal died in convulsions, and on opening the body, to the writer's surprise, he found the stomach perforated and generally softened. Blood normal.

In another experiment, two ounces of a cold saturated solution were injected into the stomach of a rabbit. After one hour death, with convulsions, ensued. The blood coloring-matter was not decomposed, but the corpuscles were markedly shrivelled and distorted, and the mucous membrane of the stomach and intestines was softened and inflamed. The kidneys were congested, and contained hemorrhagic spots. Seemingly, on account of the rapidity of its action on the stomach and kidneys, the blood color had not yet been seriously affected. Dr. Fowler concludes that potassium chlorate may kill, either by its local corrosive action on the alimentary canal, by its destructive effect upon the coloring matter of the blood, or by its inflammatory effect upon the kidneys.

DR. CASTLE, of New York, said: There is one phase of this subject to which I shall refer; that is, the local poisonous effect of chlorate of potassium. It has been stated in a foreign journal that the chlorate of potassium was introduced into medical use through a mistake in nomenclature, and that chloride of potassium is the drug to be used. I see no reason why the chloride of potassium should be any more efficacious than the chloride of sodium. A solution of salt in hot water, used in large quantities, is of service in local inflammation of the mucous membrane of the throat. In my hands, the use of chlorate of potassium usually makes a sore throat worse.

DR. LEWIS thought the reason that poisonous effects from the use of chlorate of potassium were so frequently reported was because the drug was handled so carelessly, and that if other remedies were used with the same want of care, they would be far more deadly than they now are.

AFTERNOON SESSION.

The first paper was read by DR. EDWARD H. PARKER, of Poughkeepsie, and was on *The Establishment of Hospitals in Small Cities*. He described the history of the St. Barnabas Hospital at Poughkeepsie through its thirteen years of growth.

DR. E. VAN DE WARKER, of Syracuse, then read a paper on

A NEW METHOD OF PARTIAL EXTIRPATION OF THE UTERUS.

He opened with the argument that in the operation for total extirpation of the uterus through the vagina the knife had reached its limits of usefulness, and if it could afford no better ultimate results than total mammary extirpation by the knife for carcinoma, its large direct fatality would stand in the way of the general usefulness of the operation. Uterine carcinoma called for more extensive and thorough removal than any operation yet practised, except total extirpation. We were therefore obliged to resort to some other agent. Dr. Sims had taught us how to apply a chemical caustic on dossils of absorbent cotton, wrung dry of all superfluous fluid, thus making the use of these agents as manageable for the uterus as a caustic paste was for the cancerous breast. Having the means, then, why not slough out the cancerous uterus as completely as though it were the breast? This, the author believes, he has accomplished.

The operation consists, first, of removal of the uterine cervix to the vaginal junction by the knife or scissors, and then excising the substance of the cervix as high as the internal os, in many cases relying on the curette, packing the cavity so made with cotton saturated with a twenty-five per cent. solution of subsulphate of iron, to guard against hemorrhage and harden and prepare the part for the chemical caustic. The astringent dressing is removed on the second day, and the excavation packed with dossils of cotton wrung out of a one hundred per cent. solution of chloride of zinc. A slough, varying from three-eighths to one-half inch in thickness, is the result, which is not removed by any force, but allowed to be cast off spontaneously. During this stage, hemorrhage is liable to occur, which is easily checked. The caustic has a sort of selective power, the debased carcinomatous tissue not being able to resist its action, while normal tissue, by throwing out a line of hyperplastic tissue, resists the destructive action. The line of demarcation is as fine as though cut by a knife.

In the cases cited, judging by the amount of tissue removed at the preliminary operation, and the quantity and shape of the slough cast off, there was no doubt that the entire uterus had been shelled out of its peritoneal envelope. Nothing could exceed the amount of uterus removed, except the operation of total extirpation. By means of microscopic sections, the destructive process of the chloride solution was demonstrated. It destroyed tissue by solidifying the fibres and coagulating the fluids, by combining with the water present in all tissue. Parts of low vitality are thus devitalized, but not disintegrated. Sections of sloughs, stained by logwood and mounted in Canada balsam, show the ultimate structure perfect in all its histological relations, as though it was prepared by solutions of chromic acid and spirit, for histological work. Cases were cited demonstrating the method.

DR. E. CURTIS, of New York, presented the

REPORT OF THE COMMITTEE ON EXPERIMENTAL MEDICINE,

stating that no bill had yet been introduced into the Legislature, and offering a resolution recognizing the importance of experiments on animals. Adopted.

DR. L. E. FELTON, of Potsdam, read a paper on the

VALUE OF ELECTRICITY IN DIAGNOSIS.

From an experience of ten years he was convinced of the value of electricity in the diagnosis of disease where

motor paralysis was a symptom. In these examinations it is necessary to be well acquainted with the normal response of the muscles. Different muscles react differently to the current, in regard to the strength of the current and the character of the contraction. The positive pole should be placed at some point where it cannot directly influence the muscle or the nerve. The negative pole is placed over the muscle or where the nerve enters the muscle. At this point the strength of current required to produce contraction is much less than at any other point. To find this point the electrode is moved down the muscle until it reaches a point where contraction is produced more easily than at other points. The negative electrode should be small, while the positive electrode should be large. The coverings of the electrodes should be thin. Sponges are not to be recommended. The pressure should always be the same. The thickness of the skin makes considerable difference as to the effect upon the muscles, a thick skin offering a much greater resistance than a thin skin. Cold extremities present a greater resistance than warm extremities: but when the circulation is restored they respond normally. Stimulating applications to the skin diminish the resistance. Anything that produces hyperæmia will give the same result. An eruption or a pimple will have the same effect. Unless the physician is cognizant of these variations, errors will be liable to occur. He then described a delicate galvanometer, which he had devised to determine the strength of the current employed. From his experience, he had come to the conclusion that functional diseases do not usually diminish the reaction of the muscle. Where this occurs, organic disease should be suspected. On the other hand, in some cases of organic disease, the reaction is often normal, and sometimes exaggerated. Where faradic reaction is greatly diminished, the galvanic reaction may be marked.

THE PRESIDENT announced the following as

THE COMMITTEE ON NOMINATIONS.

From the Society at Large.—E. H. Parker, M.D., of Poughkeepsie.

First Senatorial District.—Laurence Johnson, M.D.
Second Senatorial District.—George C. Smith, M.D.
Third Senatorial District.—F. C. Curtis, M.D.
Fourth Senatorial District.—L. E. Felton, M.D.
Fifth Senatorial District.—H. G. Du Bois, M.D.
Sixth Senatorial District.—W. W. Crandall, M.D.
Seventh Senatorial District.—Darwin Calvin, M.D.
Eighth Senatorial District.—John O. Roe, M.D.

THE MEDICAL FACULTY OF THE UNIVERSITY OF NEW YORK.

DR. W. C. WEY, of Elmira, offered the following:

Resolved, That a bill to establish the Medical Faculty of the University of New York be, and hereby is referred to the Committee on Legislation, with instructions to report to the Society to-morrow morning, when the order for the report of said Committee is reached.

DR. A. JACOBI, of New York, then read a paper entitled

CONGENITAL LIPOMA.

These tumors, unlike lipoma occurring in the adult, are usually devoid of a capsule; they are therefore more diffused. Some are uncomplicated with, others are complicated with, vascular tumors; others with dermoid tumors, fibroma, formations of bone or cartilage, and in one case presented, the lipoma was complicated with spina bifida. The locality varies, many are found on the extremities. The hands, and still more the feet, furnish the largest number. Several cases of the affection were then reported.

THE REGULATION OF THE PRACTICE OF MEDICINE.

DR. POWERS, of Ontario, Canada, was introduced and made some remarks in regard to an Act regulating the practice of medicine, recently passed in Ontario. The Act requires an examination previous to matriculation; four years of study at a medical college, and the examination by a board independent of all teaching bodies. No degree from any part of the world will license a person to practise in Ontario.

DR. T. R. POOLEY, of New York, reported

TWO CASES OF ORBITAL CELLULITIS.

The first one was in a child of ten years, in whom the inflammation appeared without any apparent cause. Under proper treatment, the child recovered in ten days. The second case was in a young man, the subject of syphilis, who was at the time suffering from some secondary symptoms, and had stricture of the urethra. This case was so severe that the propriety of making incisions into the orbit was considered; but the use of warm applications proved so efficacious that this did not become necessary.

The inflammation appears with a chill, and sometimes vomiting, and there may be delirium and convulsions. The onset is marked by protrusion of the eyeballs, which usually occurs suddenly. This may be moderate or excessive. It is usually directly forwards. Diplopia may occur at any stage from interference with the muscles. Swelling of the eyelids is one of the earliest symptoms, the upper lid being usually most swollen. If the orbital inflammation result from disease of the antrum or dental caries, the lower lid may be the one involved. Chemosis and swelling of the conjunctiva is an early symptom. Mydriasis is very constantly present, although myosis sometimes occurs. There is sometimes sloughing of the cornea. The most important effect, however, is that produced on vision. It may cause amblyopia or amaurosis. It has been said that this is due to atrophy of the optic nerve, which has been preceded by atrophy.

Dr. Pooley then related a case which had come under the observation of Dr. Knapp, and presented illustrations of the ophthalmoscopic appearances of the fundus. It was suggested that the loss of vision might be due to thrombosis of the veins or central or retinal artery.

The treatment of orbital cellulitis should consist in the use of warm applications. As soon as the swelling and exophthalmos subside, the cure will be assisted by the application of a pressure bandage. When suppuration appears, the pus should be evacuated at the most dependent point, provided softening is not detected at some other point. The opening is perhaps best made through the lid, and should be made in the line of the fibres of the orbicularis muscle. It may be made through the conjunctiva.

DR. L. JOHNSON, of New York, presented

A PLEA FOR THE PHARMACOPŒIA,

in which he denounced the use of preparations made according to formulæ peculiar to certain manufacturers, and recommended that instead of prescribing such preparations, the profession should adhere to the preparations provided by the pharmacopœia, except in those instances in which these proved inadequate.

DR. JACOBI agreed with the author of the paper and thought that the article would have been more complete if he had also referred to the advertisements of these preparations which fill the medical journals. It might be said that if these advertisements were excluded the journals could not exist. In many cases this would result in the abolition of two nuisances.

DR. MITTENDORF, of New York, thought the evil a growing one. The Board of Pharmacy of the State of New York are preparing a list of formulæ so that the physician will be able to prescribe remedies in an elegant and pleasant form without having recourse to these objectionable preparations.

DR. CASTLE said that he had always discouraged the adoption of any set of formulæ not officinal. The preparation of these formulæ is more in the interest of the pharmacist than in that of the physician. Its object is to do away with the necessity of keeping the same preparation, put up by half a dozen different firms and have one preparation only.

THE COMMITTEE ON THE PRESIDENT'S ADDRESS,

then reported, and presented the following resolutions embodying some of the suggestions made by the President.

Resolved, That hereafter the President shall appoint the Business Committee in advance of the annual meeting, and at as early a date as possible for the purpose of securing scientific papers for the next annual meeting; that the President be made a member of this Committee ex-officio; and that the Business Committee suggest questions to be discussed, and that one hour be set aside for an omnibus meeting in which individual experiences may be related, and queries propounded.

Resolved, That in the case of a vacancy occurring in any committee, the President be authorized to fill such vacancy.

The resolutions were accepted and referred to the Committee on By-laws.

COMMITTEE ON NECROLOGY.

DR. J. G. FISHER, of Sing Sing, presented a resolution as follows:

Resolved, That the Committee on Nominations of this Society annually nominate a Committee on Necrology, consisting of three members, who shall prepare suitable biographical notices of such members as become deceased during the year, and these notices shall be published in the *Transactions* without further reference. Referred to the Committee on By-laws.

DR. ALBERT VANDERVEER, in his paper on

OPERATION FOR CLOSURE OF THE HARD AND SOFT PALATE, WITH RESULTS,

said: It is my intention to follow this brief paper with a series of questions addressed to such surgeons as are interested in congenital deformities of the mouth; with a view of ascertaining, if possible, what percentage of cases are really benefited by the various operations, as well as the success attending mechanical contrivances. The subject of cleft of the hard and soft palate, is one that is not so settled in the minds of surgeons as to exclude further elucidation; and while it is hardly safe for one to advance much that is new, I am convinced that more careful examinations and reports of our cases one or two years after the operation are needed.

It will ever remain a source of regret to the profession that such successful operators as Warren and Fergusson—the latter having operated in over three hundred cases—did not leave a more correct record as to the results. In a clinical lecture, published in the *American Clinical Lectures*, I have presented the different steps and manner in which I prefer to operate; the method being strictly that of Sir William Fergusson's, whom I have seen operate a number of times. I consider the operation for the closing of a complete cleft a different one, and there is more or less danger attending it from hemorrhage and the great and rapid secretion of mucus, which is liable to fill the bronchi, and suffocation ensue. Still, I have never been obliged to discontinue an operation by reason of the former, and have been only once deterred by the latter. In the second attempt I put the patient upon belladonna, with excellent effect.

In alluding to anæsthetics, he said: This is one of the few operations in which, when done in childhood, I regard chloroform as safe. I never use it in any other operation, and not in this after ten years of age. Regarding the age for successful operations, I believe that, if we could obtain honest statistics, we should find that the best time for operating is immediately after the first dentition—say, when the child is about two years old; and I am also of the opinion that if no attempt is made to have the child talk, there would be less danger of acquiring that nasal twang which is so difficult for an older person to overcome.

In double harelip, the treatment of the island, or intermaxillary bone, has been dwelt upon by various writers. He said: I am convinced that, of the different complications, it is in this one that experience is of the greatest value, and that every case presents one or more peculiar features; and that the same condition is not to be seen again in a number of cases; to save this island when possible is, I think, good surgery.

As to the manner of closing the single harelip, there need be little difference in opinion. The law is flexible that to obtain good results the vermilion border must be always on a line (projecting a little, if possible); if not, apparent notching occurs.

In conclusion, he stated that we ought to be careful not to promise too much; and yet, encouragement should be given when there is hope. He reported several cases in which the results were exceedingly gratifying, the restoration of speech being perfect; others, in which marked improvement occurred, with very few cases of actual failure.

DR. G. R. FOWLER, of Brooklyn, thought it a serious question when a patient of this kind presents himself, whether or not anything should be done. His experience is limited to three cases of operation on the hard and soft palate. He had not perceived the slightest advantage from the procedure. In one case he after-

wards perforated the palate for the introduction of an obturator. This was an adult. It was worn with benefit. As is well known, it is necessary to fasten the apparatus to the teeth, and from this resection of the gums frequently occurs. I wish to confirm what Dr. Vanderveer says, that unless the patient can be operated on early in life, but little benefit can be derived from the operation.

DR. HUTCHINSON, of Utica, reported a case of double harelip, and described a procedure which he had adopted for keeping the edges of the wound together, by means of a silver wire secured by means of a large shot on the inside of the mouth, thus avoiding the risk of producing a scar from the cutting of a stitch fastened externally.

DR. GERSTER, of New York, drew attention to one point not mentioned in the paper. In regard to deciding whether an operation was justifiable, he did not think that the improvement of speech was the only point to be considered. The wearing of an obturator requires a great deal of attention in regard to cleanliness. One source of annoyance in this condition is the passage of food through the opening into the nose, and its escape through the nostril. The operation, of course, removes this difficulty. In his experience of eleven cases, three were congenital. One of these was successful. This was a case of double, complete fistula. This patient was benefited to a certain extent, as regards speech. The other cases were not benefited to any great degree.

DR. POWELL said that in 1879 he operated on a young girl. Six months later he instituted a course of voice-training, and the voice has since improved very greatly.

DR. CREVELING, of Auburn, thought that if the cheeks were dissected very freely there would be no difficulty in bringing the edges together.

DR. WARD said that he had now operated or been an assistant in fifteen or sixteen operations involving the hard palate. In adults the voice was not much improved. If only the difficulty in regard to the escape of food and liquids through the nose were overcome, the operation would be a justifiable one.

DR. VANDERVEER said that in regard to the traumatic and acquired form of the disease, the paper had no bearing on this point. In syphilitic cases, although the patients have been selected with great care, and were in good condition, the majority turned out unsuccessfully.

DR. GERSTER asked if Dr. Vanderveer had made use of periosteal flaps in the operations on syphilitic cases? Dr. Vanderveer replied that he had.

DR. WEBSTER, of New York, then read a paper on

SYMPATHETIC SEROUS IRITIS.

DR. MITTENDORF, of New York, protested against some of the teachings presented by Dr. Webster. He would never consent to wait another day if the eye were blind. Dr. Webster reports his case as a curiosity, and it is a curiosity for sympathetic iritis to recover. A delay of twenty-four hours will often lead to the loss of an eye. The slight inconvenience of a little purulent discharge from the use of a false eye cannot be compared to the risk of losing both eyes.

DR. DANIEL LEWIS, of Albany, then read a paper on

HORSE-HAIR DRAINAGE.

The hair was prepared by washing thoroughly and immersing in a solution of carbolic acid, and before using it is moistened. The advantages claimed were that it can be readily procured, it is not irritating, and the size of the drainage-tube can be diminished at will by the removal of some of the hairs.

DR. MOORE, of Rochester, regarded horse hair as one of the best materials for drainage, and also referred to the advantage which it afforded of readily diminishing the size of the drainage material.

DR. W. W. POTTER, of Buffalo, next read a paper on

DYSMENORRHŒA; ITS TREATMENT BY DILATATION,

of which the following abstract is presented:

1. That, in dysmenorrhœa, pain bears no special relation to the calibre of the cervical canal. In other words, though the channel of exit may possess sufficient patency to convey the menstrual fluid outwards with freedom, it is not a contraindication for the use of the dilator.

2. That the ready passage of the uterine probe or sound is not sufficient proof that the uterine orifices are free enough to contraindicate the necessity of dilatation. Cervices of large calibre often demand dilatation for the relief of dysmenorrhœa.

3. That anteflexion and stenosis, though frequently coexisting with dysmenorrhœa, are by no means always in the relation of cause and effect to the malady, but are, quite as frequently, mere coincidences of it. Many women have one or the other condition, and yet do not suffer with painful menstruation.

4. That the complications of dysmenorrhœa known as hystero-neuroses — the reflexes of the disease itself — frequently obscure the real malady to such an extent as to mislead in both diagnosis and treatment; but these are the cases, belonging as they do to the neurotic variety of the disease, which generally derive great benefit from dilatation.

5. That in the neurotic form of the affection the structures about the internal os will, speaking generally, be found very sensitive, considerably thickened, especially along the anterior wall of the cervix; near the os uteri internum, dense and hard, resisting the dilator with considerable obstinacy. This hyperæsthetic structure appears to be the real seat of the neurosis.

6. That in the neurotic form of dysmenorrhœa the indication of treatment is to stretch out this hypertrophic and hyperæsthetic tissue, with a view to obtain its resolution and absorption. When this is accomplished, the structures near the orifice of exit, *i. e.*, both above and below the so-called internal os, do not as readily take umbrage at the phenomena of menstruation, and thus the patient happily escapes the pain which has heretofore been associated with the performance of this function.

7. That for this form of the malady moderate consecutive dilatation, with graduated vulcanite or metallic bougies, possesses advantages over the more radical method with the two-bladed expanding dilator, which completes its work at a single sitting: for, whereas the latter instrument stretches the parts laterally, thereby increasing the transverse diameter of the channel of exit only, the former not only dilates the entire lumen of the passage, but, what is of even greater importance, by steady and repeated pressure, it promotes absorption of the hardened and thickened tissues wherein resides the neurosis.

8. That to secure success of the measure it is important that firm fixation of the uterus should be obtained, either by double tenaculum or volsellum, and to this end the Sims's speculum and the semi-prone position are indispensable. The single tenaculum will often tear out, and, besides, does not hold the cervix with sufficient firmness. In many cases an anæsthetic will be required, but, when possible, it should be omitted as unnecessarily complicating the procedure.

9. That it is of less consequence to make the dilatation extreme than to do it well. A moderate amount of stretching, properly done at regular intervals, seems to secure better ultimate results than a more radical single dilatation of the passage.

10. The theory is offered that the dilators relieve the suffering from the agonizing pain of the malady much on the same principle that nerve-stretching relieves ordinary neuralgias.

11. Finally, let it be remembered that the foregoing remarks are intended to apply, particularly, to a class of cases which may be designated as neurotic, or belonging to the neurotic form of dysmenorrhœa, in which the channel of exit, though apparently large enough to carry off the menstrual flux, nevertheless possesses little or no resiliency, and in which, furthermore, at the point where the uterine cavity merges into the cervical canal the tissues are thickened, metamorphosed, and hyperæsthetic.

The following papers were read by title:

Two Cases of Rupture of the Heart, by DR. T. H. SQUIRE, of Elmira.

Biographical Sketch of the Late James Rushman Wood, M.D., LL.D., by DR. FREDERICK S. DENNIS.

Biographical Sketch of the Late Dr. J. F. Jenkins, by DR. G. J. FISHER, of Sing Sing.

Biographical Sketch of the Late Dr. G. W. Bradford, by DR. C. GREEN, of Homer.

The Medical Society of the State of New York in its Relation to Sanitary Science and Public Health, by DR. E. HARRIS, of Albany.

Biographical Sketch of the Late Dr. James S. Bailey, by DR. J. C. CURTIS, of Albany.

EVENING SESSION.

DR. PIFFARD called up the communication from

THE ONTARIO COUNTY MEDICAL SOCIETY,

which had been laid on the table at the morning session.

THE CODE OF ETHICS.

Dr. Piffard moved that it be placed on file, and that the Secretary be instructed to notify the Ontario County Medical Society that any by-law adopted by that Society, which is not approved of by this Society, will have no legal force.

The statute of 1880 provides that county medical societies shall make such rules and regulations as they may desire, provided the action of such society receive the sanction of the State Society. The adoption of the Code of Ethics of the American Medical Association is not approved of by this Society, and therefore a by-law to that effect cannot be legal.

DR. CRITTENDEN, of Ontario, said that the object of the resolution was that the delegates from this county should use all honest means to influence the State Society to repeal what is called the New Code. It has nothing to do with a by-law.

DR. PIFFARD did not assume that this communication was presented with such an object, but many of the County Societies think that they have the right to adopt any by-law that they wish. Such is not the case. In order to be enforcible, it must receive the sanction of the State Society.

The motion was passed.

THE DELEGATE from NIAGARA COUNTY presented a series of resolutions in favor of the National Code of Ethics, which was received and ordered to be entered on the minutes.

DR. PIFFARD moved that if there be nothing further in the special order of business, the routine business of the Society be taken up.

DR. MOORE, of Rochester, said that we came here for a special purpose. Everybody knows what it is for. I had not intended to say anything. I supposed that Dr. Didama would be here and bring forward the resolution presented last year. In the absence of Dr. Didama, I ask for the reading of this resolution.

The resolution was read as follows:

Resolved, That all action taken at the annual meeting of 1882, in regard to changing the CODE OF ETHICS be repealed, leaving the CODE to stand as it was before such action was taken.

DR. T. F. ROCHESTER, of Buffalo, moved the adoption of this resolution, and in making the motion, he said: I do it with the hope of restoring the unity, harmony, and good feeling of the proudest society in the Union. I hope that the remonstrances which have been sent in from the county medical societies will not simply be tabled, and no attention paid to them. That was done last year. I think that perhaps we have all given way too much to our personal feelings. I think that on both sides party ties have been stronger than they should be, and not in the interests of harmony. We should try to do what is best for the profession at large. I believe that there is a very strong feeling in the profession against the existence of the New Code of Ethics. If we go back to its inception, we find that when it was passed there were only seventy members present, nevertheless it was legally passed.

At Cleveland, last year, the attempt was made to do what should have been done before the State Society took the position of seceding from the American Medical Association. The question as to whether any modification of the by-laws was necessary should have been brought before the American Medical Association. The attempt was made in that direction last year, but the motion would not be entertained for a moment, because this Society was in a state of rebellion. I do not believe that such a motion will be entertained as long as the New Code prevails; but I do believe that if this Code should be repealed and the Old Code restored, the members of this Society could bring the matter before the American Medical Association, and it would be received and acted upon.

DR. H. D. DIDAMA, of Syracuse, made a few remarks in the same spirit as those of Dr. Rochester, and asked, in the interests of harmony and the good of the profession, that the New Code should be repealed.

DR. ROOSA, of New York, stated that it was the intention of those who were in the majority in the City

and in the State of New York to allow the voting on this question to proceed without any remark, but since at least two new arguments or elements have been presented to the Society, both in its meetings and through the columns of the daily press, it seems proper to refer to them. The one argument is based on a threat which we hear whispered, that, unless certain circumstances occur, a new State Society is to be organized. They come to the meeting with the olive-branch in one hand and the hatchet in the other. This is the harmony of which they speak.

Dr. Jacobi, of New York: I simply call for the question, as I am sure that the members here have come for the purpose of voting, and that not a single word that has been spoken will have any influence.

Dr. Moore, of Rochester, said that he considered it very dishonorable for a Society, after agreeing to certain articles, to throw them off and contemn them, without consultation with the sister States, in connection with whom they were adopted.

The question was again called for. The result of the vote was 105 in favor of the repeal of the New Code, and 125 in opposition.

NO CODE.

Dr. Roosa: Inasmuch as I stated that if a proper opportunity should again occur I would give the members a chance to vote on the abolition of all codes, if any one who voted in the minority makes this motion, I will second it.

Dr. Jacobi: As no member seems willing to profit by the invitation, although I did not vote with the minority, I move the adoption of the amendment as follows:

"The Medical Society of the State of New York, in view of the apparent sentiment of the profession connected with it, hereby adopt the following declaration, to take the place of the formal Code of Ethics, which has up to this time been the standard of the profession in this State:

"With no idea of lowering, in any manner, the standard of right and honor in the relations of physicians to the public, and to each other, but, on the contrary, in the belief that a larger amount of discretion and liberty in individual action, and the abolition of detailed and specific rules, will elevate the ethics of the profession, the medical profession of the State of New York, as here represented, hereby resolve and declare, that the only ethical offences for which they claim, and promise to exercise the right of discipline, are those comprehended under the commission of acts unworthy a physician and a gentleman.

"*Resolved*, Also, that we enjoin the county societies and other organizations in affiliation with us, that they strictly enforce the requirements of this code."

Dr. Agnew then described the working of the committee that had formulated the New Code.

Dr. Jacobi: When I made this motion I did not expect that it would excite much discussion; I did not want to keep the Society until three o'clock. But as it seems likely to do so, I request that the meeting allow me to withdraw my motion.

A motion was made to this effect, but its seconder, Dr. Furbeck, declined to consent to its withdrawal.

A motion to adjourn until 10 A.M. was then put and carried.

Wednesday, February 6th, Second Day.

Morning Session.

After the reading of yesterday's minutes,

THE TREASURER'S REPORT

was presented, exhibiting a balance of $1462. The report was referred to the Auditing Committee.

Dr. W. C. Wey, of Elmira, presented a

REPORT FROM THE COMMITTEE ON BY-LAWS,

with a resolution that the Committee on By-laws be instructed to prepare a scheme for the government of County Medical Societies, which shall be in conformity with the laws of the State of New York and of this Society, and to forward it to the County Societies.

Dr. Jacobi, of New York, from the

COMMITTEE TO COÖPERATE WITH THE SOCIETY FOR THE PREVENTION OF CRUELTY TO CHILDREN,

reported that a hospital for diphtheria and scarlet fever had been organized in New York, and would soon be ready for occupation. The Committee offered the following resolution, which was adopted:

Resolved, That the State Medical Society deeply regrets the failure of the Legislature last year to enact the law proposed by its committee for the protection of children engaged in factory work, and respectfully commends the subject to the attention of the present Legislature, with the hope that definite action will be had in the matter, which is of grave importance and deep interest to all humane persons.

PRINTING THE MINUTES.

Dr. Piffard, of New York, offered the following:

Resolved, That the Secretary be authorized to have printed a sufficient number of copies of the business proceedings of this Society to supply every member with a copy, and that a sufficient number be sent to the secretaries of the county societies for the use of their members. Adopted.

Dr. E. V. Stoddard, of Rochester, from the

COMMITTEE ON HYGIENE,

reported that during the past year there had been no tendency to any general epidemic. Measles of a mild type had prevailed. Attention was called to the lack of proper precautions to prevent the spread of contagious diseases.

Dr. F. R. Sturgis, of New York, from the

COMMITTEE ON LEGISLATION,

reported the draft of an Act, of which the following are the main features:

Section 1. The Governor shall appoint the Medical Faculty of the University of the State of New York, to consist of nine members, who shall be authorized practitioners of physic and surgery in this State, but none of whom shall be connected with any medical school or college which grants the degree of M.D.; provided, that in the appointments made the representation of the several systems of medical practice recognized by the incorporated medical societies of this State shall be in the proportion of six, two, and one, that is to say, the system having the oldest date of incorporation to have six, the next oldest to have two, and the remaining one to have one representative; and all persons desiring to enter upon the practice of physic

and surgery in this State, after November first, eighteen hundred and eighty-four, shall, before doing so, comply with the provisions hereinafter prescribed, and obtain the license hereinafter provided.

Sect. 2. Of the nine members of the said medical faculty, three shall serve, in the first instance, for three years, three for four years, and three for five years; and these terms shall be severally distributed by lot at the first meeting of the said faculty. All appointments made in the faculty at the expiration of the several terms fixed above shall be made uniformly for the period of five years each. All vacancies occurring in the said faculty, from whatever cause, shall be filled by the Regents of the University, on the basis arranged in Section 1; in case the several State medical societies shall nominate physicians to fill such vacancies, the Regents shall appoint some one of the physicians so nominated. The Regents may, for cause, remove from office any member of the faculty, after due notice, and an opportunity to be heard.

Sect. 3. The said medical faculty shall examine all applicants for license to practise physic and surgery in this State. The members thereof shall meet at least semi-annually, and at such meetings shall faithfully examine all candidates referred to them for that purpose by the Chancellor of said University, and each furnish him a report in writing of his opinion as to the qualifications and merits of each candidate, referring briefly to the degree of proficiency evinced by the applicant in the branches in respect of which he was examined by him; which opinion shall be by him denominated favorable or unfavorable.

Sect. 4. Such examination shall be in anatomy, physiology, histology, pathology, theory and practice of medicine, chemistry, surgery, obstetrics, materia medica and therapeutics, and such other branches in the several departments of medical science as the said faculty may agree upon, subject to the approval of the Regents of the University.

Sect. 6. Any person, on paying fifteen dollars into the treasury of the University, and on applying to the Chancellor for the aforesaid examination, shall receive an order addressed to the aforesaid medical faculty, instructing them to examine the candidate.

Sect. 7. The Regents of the University, after finding that seven or more of the members of said faculty participating in the examination have given an opinion in favor of a candidate, shall issue to him or her a license to practise physic or surgery in the State of New York, for which license the candidate shall pay to the University the further sum of ten dollars. Said faculty may refuse to recommend a license to any individual guilty of dishonorable or criminal conduct, and for like cause, after giving the accused an opportunity to be heard in his or her defence, the Regents of the University may revoke said license.

Sect. 8. The moneys paid to the University under the provisions of this Act, shall be appropriated by said Regents for, and shall defray all expenses incurred under the provisions of this Act.

Sect. 9. Of the medical faculty, seven members shall constitute a quorum.

Sect. 10. Subsequent to the first day of November, in the year eighteen hundred and eighty-four, every person (except such as have before such date lawfully registered pursuant to the laws of the State in force at the time of the passage of this Act), after complying with Sections six and seven of this Act, shall, before commencing to practise physic or surgery, register in the clerk's office in the county where he or she practises or intends to practise physic or surgery. Nothing in this Section shall be so construed as to prohibit medical consultations in the different counties of the State between legally qualified and registered physicians of this and other States.

DR. PIFFARD, of New York, moved that the report be accepted and entered on the minutes.

DR. C. R. AGNEW, of New York, asked why no report had been made on the bill presented yesterday by Dr. Wey, and referred to the Committee on Legislation. He moved that the report of the Committee be laid on the table.

DR. ROOSA raised the point of order that Dr. Piffard's motion was before the house, and that it must be disposed of before another motion could be entertained.

THE PRESIDENT decided the point well taken.

Dr. Piffard's motion was then adopted.

DR. AGNEW then moved that the Committee on Legislation be instructed to act upon the order of the House in regard to the bill presented by Dr. Wey.

DR. ROOSA objected that it was not courteous to the committee to try to force upon it a bill which, otherwise, it would not have entertained. There was nothing, he said, to prevent any member from introducing any bill he might desire.

DR. PIFFARD stated that, according to the by-laws, all resolutions touching medical legislation must be referred to the Committee on Legislation, who shall make a report.

DR. STURGIS said that the resolution had not been received by the Committee from the Society; if it had been, it would have been entertained.

Dr. Agnew's motion was then carried.

The Committee on Legislation then made a supplementary report embodying the bill presented by Dr. Wey, of which the following are the main features:

Section 1. From and after the first day of June, 1884, there shall be and continue a Medical Faculty of the University of the State of New York, consisting of nine members, appointed by the Governor, and no member thereof shall be or become connected with any medical school or college. Except as otherwise hereinafter provided, the members shall each hold office for five years.

Sect. 2. Upon the written recommendation of three-fourths of the Medical Faculty, the Governor may remove from office any member of the Faculty.

Sect. 3. From and after the first day of November, in the year 1884, no person not theretofore lawfully authorized to practise physic and surgery in this State shall enter upon or be admitted to such practice unless lawfully licensed, after examination by or under the supervision of the Medical Faculty, in the manner hereinafter provided, or unless regularly authorized by the diploma of some legally incorporated medical school or college in this State.

Sect. 4. From and after the first day of November, in the year 1884, excepting persons regularly authorized by the diploma of some legally incorporated medical college in this State, and except as provided in the seventh section of this Act, any person not theretofore lawfully

authorized to practise physic and surgery in this State, and desiring to enter upon such practice, may, upon payment of twenty-five dollars into the treasury of the University, deliver to the Regents of the University a written application for license, together with satisfactory proof that the applicant is more than twenty-one years of age, is of good moral character, and has received a diploma conferring the degree of doctor of medicine from some legally incorporated medical college, and thereupon the Regents of the University, through such officer as may from time to time be designated for that purpose, shall issue to such applicant an order for examination by the Medical Faculty.

The examination shall be in and upon the several departments and branches of Medical Science as the same shall have been designated by the Medical Faculty, with the approval of the Regents of the University.

The questions propounded shall be such as from time to time shall have been determined and designated by the Medical Faculty, subject to review by the Regents of the University, and written answers to such questions shall be required.

Sect. 6. The Regents of the University shall issue to every such applicant who shall have been so examined, and as to whom a "favorable" opinion shall have been delivered by seven or more members of the faculty participating in such examination, a license to practise physic and surgery in the State of New York. Such license shall be delivered only upon payment of the sum of fifteen dollars into the treasury of the University, and shall entitle the person so licensed to practise as aforesaid until such license shall have been revoked for cause, as hereinafter provided.

Sect. 7. From and after the first day of November, 1884, the legally authorized medical schools and colleges in this State shall issue diplomas conferring the degree of doctor of medicine and the right to practise physic and surgery within this State after examination under the supervision of the medical faculty in the following manner: Whenever any such school or college shall propose to make any such examination, it shall give to the medical faculty notice thereof in the manner which shall have been previously prescribed by the medical faculty, which shall, without delay, designate and appoint three of its members to attend such examination. The questions to be addressed to the candidates for degrees at such examination shall be submitted to the members of the medical faculty attending such examination, and all answers thereto shall be open to their inspection. The expenses of such attending members of the medical faculty, and the compensation of each member, at the rate of twenty-five dollars per diem for each day spent in going to or from, or attending such examination, shall be paid by the medical school or college at which such examination shall be had.

Sect. 8. The medical faculty may, by a two-thirds vote, after having given to the person to be affected an opportunity to be heard, recommend to the Regents of the University the revocation of any license issued under the provisions of this Act, or of any right to practise physic and surgery under any diploma hereafter issued, because of professional incompetency or misconduct, and unless the Regents of the University shall upon the record decide that such recommendation is not well founded, the license so issued and the right to practise under such diploma shall be withdrawn, from and after the time when such recommendation shall have been made by the medical faculty, and unless and until such recommendation shall have been overruled by the Regents of the University, the person accused shall not practise physic or surgery in this State, and any license issued under any former Act may be similarly revoked for unprofessional or dishonorable conduct subsequent to the passage of this Act, and after such revocation the person affected shall not practise physic or surgery within this State.

Sect. 9. The medical faculty may, by a three-fourths vote, recommend the Regents of the University to vacate, annul, or suspend the charter of any medical college or school within this State, and the Regents of the University, after giving to such medical college or school, through its trustees or directors and faculty, a proper opportunity to be heard, may, by a two-thirds vote, adopt such recommendation in whole or in part, and may vacate, annul, or suspend the charter of such medical school or college, or may make such determination or order as in the matter may seem proper, and thenceforth the rights and powers of such medical school or college shall exist, and be exercised only in subordination to such determination of the Regents of the University.

Sect. 12. Subsequently to the first day of November, in the year 1884, every person (excepting such as may have theretofore lawfully registered pursuant to the laws of the State) being licensed under sections six or seven of this Act shall, before commencing to practise physic or surgery, register in the Clerk's office in the county where he or she practises or intends to practise physic or surgery. Nothing in this section shall be so construed as to prohibit medical consultation in the different counties of the State, between legally authorized and registered physicians of this and neighboring States.

DR. PIFFARD moved the adoption of the supplementary report. Passed.

DR. STURGIS stated that the last bill reported had been considered by the Committee, and had not met with its approval.

DR. H. R. HOPKINS, of Buffalo, offered the following:

Resolved, That the report of the Committee on Legislation be accepted.

That the Committee be instructed to use all proper efforts to secure the passage through the Legislature, of the bill favorably reported, with any necessary amendments. That a copy of these resolutions, with the official signatures of the President and Secretary, be transmitted to both houses of the Legislature without delay.

He stated that the profession at large, as he thought from extensive correspondence, would endorse these resolutions.

DR. A. L. LOOMIS, of New York, said that this was an important matter affecting the profession at large, and also every medical college in the country. He called attention, in the first place, to the composition of the Board of Examiners. In the one reported unfavorably, it consisted of gentlemen not connected with any medical college. In the one favorably reported, of gentlemen not connected with a college which grants the degree of M.D. The latter recognizes certain sects in the profession. The great points of difference are in the composition of the Examining Board and the powers of

this Board. The one is supervisory, the other absolute. The Supervisory Board have power to examine men coming from outside the State and to investigate the teachings of the different colleges in the State. If these are irregular, they have the right to report to the Regents, recommending the withdrawal of their charter. It has power to silence all bogus schools. There is no such provision in the other bill. The objections to the bill reported favorably are that the Board is taken from the non-teaching body; England tried this, but it was a failure. In France, the Examining Board was taken from the teaching body. In Germany, the Board was mixed. It is said that other States have tried this plan, but in many it has failed. It is not safe to separate the Examining from the Teaching Board. In regard to compensation, we reject ten to twenty per cent. every year, but they pay the same whether they graduate or not. The compensation allowed by the bill is insufficient, not amounting to more than seven hundred dollars per member, the time required for thorough examination being not less than two months. He objected to the power over the curriculum of the college, as it gave power to theorists to insist upon the teaching of their hobby.

DR. ROOSA thought that if it was difficult to find nine men who would not insist upon teaching their theories, it would be equally difficult to obtain nine men for a Supervisory Board. We are willing to accept any amendment that does not eviscerate the Bill. I am informed that if the State Society will agree on some course of action, that there is a probability that the bill will be adopted at this meeting of the Legislature. In regard to sects, we can get no bill if one of the sects oppose it. It is objected that too much power is given to the Board, but it can be no more absolute than that now possessed by the medical faculties.

DR. PIFFARD read the proceedings of the last meeting bearing upon this subject, and referred to the history of the bills. He had heard that in a conference held recently in New York, its advocates had changed the ratio of representation from six, two, one, to five, three, and one. Seven constitute a quorum, and four or three members might declare that it was necessary that every medical college in the State should teach homœopathy. He then reviewed some of the other sections. He thought that both bills should be referred to a special committee.

DR. JACOBI thought that, if the Society would do nothing, the Legislature would take the matter into its own hands. He moved that when the Society adjourn, it adjourn until three o'clock, and that this matter be taken up at half-past four, and finally decided before adjournment; the motion was amended so that the bills be taken up at three.

AFTERNOON SESSION.

DR. L. HOWE, of Buffalo, thought that the object to be attained could be better reached through the Society itself than through the Legislature; and that the Society could appoint a committee to have supervision of the medical colleges; and he offered this

AMENDMENT.

That a committee be appointed to draft a plan whereby a Commission should be organized, whose duty it should be to attend the examinations of the medical colleges, take cognizance of the methods and the excellencies or defects of such examinations, and report the same each year at the annual meeting. The committee to report such a plan during the present session.

DR. DALTON, of New York, seconded the amendment, and spoke at length in its favor. He was opposed to legislation on this subject. Both bills presented the defect which it was one of their objects to remedy. To take away the inducement of increased fees which come with the increased number of students, the bills provide that the examining board shall be paid from the fees collected from those examinations. He did not believe that in either instance this would be the case. Either bill would diminish the efficiency of the teachers by taking from them the responsibility; also, it is evident that the balance of power is in the hand of the eclectics.

Dr. Howe's motion was laid on the table to allow of the introduction of a substitute by Dr. Hopkins, to obtain an expression of opinion by the meeting, whether or no an examining board was wanted.

DR. PIFFARD moved as an amendment to Dr. Hopkins's motion, that the matter be referred to a committee, consisting of Drs. Loomis, Curtis, and Vanderveer, with the Committee on Legislation, and that this joint committee be instructed to report a bill at the next annual meeting.

A number of members spoke in favor of the motion.

The amendment was carried, and Dr. Hopkins's motion as amended was adopted.

THE REPORT OF THE COMMITTEE ON PRIZE ESSAYS

was on motion reconsidered. A majority report embodying the features of the report made on Tuesday, was presented.

DR. W. W. POTTER, of Batavia, presented a minority report, stating that the essay to which it was recommended by the majority report to award the prize, was, in his estimation, unworthy of it. While an excellent paper, it did not reach the standard. He therefore recommended that the prize be not awarded.

DR. VANDERVEER moved that the minority report be accepted. He said that the same essay had been presented to the New York County Society, and had been rejected. It was made up largely of extracts.

The motion was carried.

DR. MITTENDORF then read a paper on

FÖRSTER'S METHOD OF RIPENING CATARACT.

It is a well-known fact that if the lens be injured it may become opaque. Acting on this, Förster advised iridectomy for the purpose of ripening senile cataract. The indications for the operation are cataract in both eyes at the same time; loss of one eye, the other becoming cataractous; where one eye is diseased, and on account of that disease cataract develops in the other eye; where the patient is going beyond the reach of skilled help. The operation consists in an iridectomy, and then gently rubbing the cornea with the blunt angle of a strabismus-hook. The after-treatment consists in keeping the patient for a few days in bed, and instilling a weak solution of atropine. Complications are to be treated as in other cases. The results are favorable. In two cases the cataract ripened in four days; in the majority

in four weeks. The operation is not entirely devoid of danger. It is to be performed in exceptional cases. In twenty patients operated on, only three had serious inflammatory complications.

DR. SHEEHAN read a paper on *House Sanitation as it is and should be.*

DR. J. B. TODD, of Parish, reported the following case of

SPONTANEOUS PYÆMIA.

A. W., aged fifty-nine, a farmer; previous health and habits good. On the morning of September 23, 1883, he had a severe chill, but he was able afterwards to ride six miles in a wagon. He was much prostrated, and fainted and vomited on the way. At night, he returned to his home. At this time his condition was as follows: Countenance shrunken and bloodless, hands stiff, complained of pain in every part of the body, and especially in the back. He was much prostrated, and could not get to bed without assistance. The temperature was 103°, and the pulse was 90 per minute.

On the 24th the feet were very painful, and felt as though they had been burned. The balls of the toes seemed inflamed; temperature 104°, pulse 95.

On the 25th, the feet were still painful, and there was a deposit of pus about the nails; temperature 102°.

On the 28th, pus was found beneath the skin of the balls of the toes; pustules and spots of ecchymosis were found on the back. He passed into a typhoid state, with semi-unconsciousness and incontinence of urine, and died on the 30th, having been entirely unconscious for the twenty-four hours preceding death.

At the post-mortem, the capsules of the kidneys were readily detached, and beneath them were found a large number of minute pustules.

The treatment consisted in the use of stimulants, with quinine, carbonate of ammonia, digitalis and opium as required, and the administration of nutritious food. It was thought that the probable explanation of spontaneous pyæmia was the formation of a thrombus in the tissues of the lung or liver, the thrombus subsequently undergoing degeneration and producing poisonous materials.

The following papers were read by title: *Care and Preservation of Medical Pamphlets*, by Dr. J. G. Fisher, of Sing Sing; *Strangulated Hernia, Five Cases Treated by Operation*, by Dr. J. Chapman, of Medina; *Notes on the Treatment of Diseases of the Digestive Organs*, by Dr. F. A. Castle, of New York; *Hay Fever*, by Dr. J. O. Roe, of Rochester.

The next paper was by DR. M. JOSIAH ROBERTS, of New York, on

THE CURE OF SPINAL CARIES WITHOUT DEFORMITY.

After describing the physiology of the joints and the necessity of some apparatus which does not fix the joint, he exhibited his apparatus, in which, opposite each joint, there is a sliding arrangement, held together by a rubber band. By this means the nutrition of the limb is increased, and a cure can be effected in one-third less time than by other means.

DR. FOWLER, after considerable experience, had discarded all bandages. He used splints of leather moulded over a plaster cast. This answers all the purposes of traction. In his hands the long Taylor splint was successful, but he had noticed that it failed to make the traction for which it has been introduced and to this failure he attributed its success.

DR. PHELPS then read a paper on

SYNOVITIS OF THE KNEE-JOINT,

and exhibited some cheap forms of apparatus which he had devised for the treatment of chronic inflammation in various joints. The principle on which extension should be applied is that the line of extension should be in the line of the deformity; in any other way, traction will cause pressure on the joint. The apparatus for the knee consists of a tin band above and below the joint, on each side of which bands a loop was soldered, through which a stick passed. The bands are secured to the limb, and the sticks inserted; the limb is then drawn out as far as is desired, and pins inserted in holes in the sticks, maintaining the extension. When powerful extension is desired, where the deformity is marked and the synovitis is old, two bands are secured as before, having a pocket at the posterior surface, which receives the end of a rod, which can be lengthened by sliding through a loop of tin, and secured by a pin. Around the knee and the stick an elastic bandage is applied; for the ankle, a foot-piece, with holes to receive iron side-pieces, is used; the upper ends of these, passing through loops in a tin band, secured to the calf, can be fastened with a pin, as in the previous cases.

DR. W. C. WEY, Chairman of the

COMMITTEE ON BY-LAWS,

reported a resolution approving of certain amendments of the Albany County Society. It also recommended that the Treasurer and Secretary constitute a temporary Committee on Credentials, until the permanent committee be appointed. Adopted.

DR. C. L. DANA, of New York, then read a paper on

MORBID SOMNOLENCE.

He reported fifty cases of morbid somnolence, four of which had come under his observation. The affection is due to different causes, such as old age, diseased vascular conditions, diabetes, dyspepsia, sunstroke, cerebral tumors, and exhausting diseases. After a time the general health is affected, and sometimes the mind gives way. The symptoms show themselves in various ways. Sometimes consciousness is not entirely abolished. The treatment should consist in remedies to remove the cerebral anæmia or hyperæmia. Exposure to sunshine, heat, and noises has been recommended. Sternutatories are recommended. Symptomatic remedies, as coffee, caffein, cocoa, belladonna, nitroglycerine, and nitrite of amyl are also useful.

THE EVENING SESSION

was held in the Assembly Chamber of the Capitol.

THE PRESIDENT, ALEXANDER M. HUTCHINS, A.M., M.D., of Brooklyn, delivered

THE ANNIVERSARY ADDRESS.

He choose for his subject

THE RECIPROCAL ATTITUDE OF THE MEDICAL PROFESSION AND THE COMMUNITY.

He said there is a medical science, but if medicine were a science only, there would be fewer medical

schools than now exist. The former part of this proposition has been denied. The impression is prevalent that, while much learning has been amassed in medical research, the results thereof are so unrelated, and the conclusions so untrustworthy as a basis for future observers, that even conceding that some of its methods are scientific, in the catalogue of the sciences it is to be classed among the empirical, and not in the exact.

Medical science assumed her unique place among the sciences when the facts and phenomena, evoked by biological research, were made the basis of investigation, whose purpose is to prolong the vital process and arrest the untoward influences that perpetually threaten its extinction. This is her distinctive mission.

The body of medical science is the slow accretion of the centuries, and the contributions to its learning are too numerous for the historic pen. The results of yesterday are the alphabet of to-day. But seventy-five years have gone since the ovarian cyst was exsected by the grave Kentuckian whose honored memory his grateful brethren have perpetuated by the granite obelisk in the Danville churchyard, and by a skilful use of exceptional opportunity the Scottish chieftain is justly credited with having added hundreds of years to woman's life; and not only that, but, wherever this literature has reached, men, whose names can never become historic, are performing this merciful task with assurance and success. But fourteen years have gone by since the turf hid the gifted German who revolutionized the operation for cataract, but even now, the great centres show a phalanx of men whose skill is greater, as their experience has increased. By the very genius of the science this history of progress and change must always be repeating. The days rapidly hasten on when the names of McDowell and Von Gräfe, of Keith, and Sims will be prominent only as landmarks.

The one hundred years have just passed since Jenner's observations and experiments in Gloucestershire associated his name inseparably with the amelioration of smallpox. Fifty years later Ehrenburg and Dujardin studied and described the various forms of monas, vibrio, spirillum, and bacterium, and the century hardly rounded before Schwann had shown that these bacteria are the cause of the putrefaction of organic substances, and Pasteur had extended this discovery so as to create the belief that all putrefactive changes are due to such minute organisms, when Lister had developed his antiseptic method based on these discoveries; when Koch propounded his theory that tubercular consumption was due to the bacillus; when erysipelas, and glanders, and splenic fever, and malignant charbon were shown to be due to special types of bacteria, and Pasteur had inoculated the attenuated virus of malignant charbon as a protection to cattle and sheep from attacks of the severe forms of the disease.

These discoveries increase rather than remove our doubts as to what lies beyond, but their far-reaching results, of which the foregoing are but hints, are the product of the present decade of investigation, and we stand but at the threshold of these directions of biological research.

The attitude of the community toward scientific study is, primarily, that of antagonism. Innovation provokes opposition. There are many years, but one sentiment, between the persecution of Galileo and the onslaught on vivisection. Popular government has never initiated any movement to promote research, for that implies a cultivated sentiment among the voters, and the English-speaking nations have done almost nothing in the way of State appropriations for scientific study. Germany, France, Russia, Holland, Belgium, and Italy are, almost exclusively, the originators of the later methods. From their laboratories have come the great discoveries of modern times, and this, because in these countries the laboratories have been under State patronage. The most that has been done in England and the United States, has been done by those men whose capacity for scientific discovery has been accompanied by the possession of private fortune; the remainder has come from work incidental to the occupation of professional chairs.

In this country, neither the nation, nor, to my knowledge, any State has done the first thing to further scientific research directly. Much has been done for industrial education, and a great deal of research is really carried on under cover of State and government appropriations, but all is of secondary moment to the powers that be.

Scarcely any provision has been made until recently for biological science in an institution of learning, beyond elementary instruction. New research is contemplated in a few, notably in the Johns Hopkins laboratory and in the investigations by Dr. Martin in Chesapeake Bay and at Hampton. This enterprise is due to private beneficence, and its results, especially in investigating the various modes of propagating the oyster, have induced the State to promote further studies in this single direction.

The cultus of medical science must continue to share the experience of all original investigation and remain a personal factor among the diverse directions of human industry. Multitudes stand ready to seize the results of its labors and apply them, in ways that men can understand, to the satisfaction of human need. They who cull the flowers, enjoy the fruit, reap the harvest or sell the crop, are of different mind and other station than they who till the ground, plant the seed, nurture the sapling and wait, through recurring seasons of sun and snow, till the sturdy limbs are shelter and refreshment to the unthinking life that recks not of its benefactors.

There is an art of medicine and its multitudinous votaries attest the fruitfulness of its pursuit.

In 1880 the States and Territories of this country held a population of 50,155,783, and of these, 85,671 persons were enumerated as either physicians or surgeons, a proportion of 1 to 585. In the State of New York there were 5,082,783 persons, of whom 9,272 were doctors, a proportion of 1 to 548. What the ample front doors of the medical colleges, with the signatures of numerous licensing bodies, have done, during the past four years, to swell the total, it would be hazardous to speculate upon. But these salutary, health-forecasting and longevity-producing statistics stamp the effete and tottering governments of Europe with the die of derision, in their infamous disregard of human comfort, and put an extra gilding on Columbia's protecting ægis, prolonging the beauty of her daughters and the bravery of her sons; for while the proportion of doctors to population in Switzerland is 7.06 per 10,000, in Italy 6.10, in Hungary 6.10, in England 6, in Austria 3.41, in Germany 3.21, and in France 2.91, the United States with her 17.1 per

10,000 have consummated what Berkely foresaw, but did not dare to write—

"Westward the doctor's empire has full sway."

It is asking too much of credulity to believe that the attitude of the profession is friendly to the community, when the lavish gift of the doctorate puts into so many undisciplined hands the medical arts which are as potent for evil as for good.

Humiliating and unsavory though it be, the pregnant fact holds true, that, coupled with that large body of men who acknowledge an ancestry of scholars and faithful students of nature, who base their art on principles which have survived criticism, who practise their art in the interest of the physical and spiritual well-being of their fellow-men, whose livelihood is a legitimate product of their worthy and acceptable service, there is another and large class, known not only to the census enumerator but to the community, by the same name, with equal protection under the law, who, with insufficient culture and consciences dulled through habitual and ignorant tampering with grave responsibilities (described lately by an influential medical journal as "hangers-on of whom any party would be ashamed"), who are a standing menace to the community, which, accepting all as competitors in the race, gives to all alike its patronage and its support.

While the history of research has proved that the community has been slow to recognize its duty to scholars, in facilitating their inquiries into the facts and phenomena of physical life, which have developed laws and expedients so important and far-reaching in their influence on the well-being of the race; yet the contrary holds true in the attitude the community sustains to medical art. Certainly, in this country at least, in the broadest sense, up to the limits of its education, the community has been a lavish patron of the agencies that alleviate disorder and a co-worker in enforcing the instrumentalities which prevent disorder.

Certainly the community is not slow to accept the offers of mercy, for while it submits patiently to all that is ordered by the profession, takes all its medicaments, undergoes all its operations, awaits the results of all its experiments, and, unhesitatingly, believes everything it says, and quotes it, more or less correctly, for the neighborly benefit; the community, in its charity towards all, does not allow the profession monopoly in the practice of medicine, but, with its faith in drugs, and measuring their efficacy by the violence of their operation, it swallows on bare printed promises $60,000,000 in proprietary medicines per year, and assists the fortunes of drug dealers to the extent of $80,000,000 per annum more.[1]

It is estimated that three-fourths of those enumerated as physicians and surgeons are up to the limits of their individual competency, applying to the healing of human ills the best methods of experience, based on the knowledge derived from scientific research. The remaining 20,000 are an *olla podrida* of every conceivable specialty, having the common bond of applying each his own special method of cure to all diseases. The particular mode of cure is the trade-mark to attract patronage. If any is honest enough to vary his method of cure, with the hope of benefit to his patron, he is dishonest to his advertisement. If any are so bigoted as to believe that one mode of cure is applicable to all diseases, or if any are so rigidly adherent to their special trade-mark as to apply it to all, regardless of all consequences save their personal gain, the community is not only defrauded but damaged. It would be idle to deny that each trade-mark covers some truth, or that some useful thing has been the stock in trade of some peripatetic healer, as witness the carbolic acid injection for hemorrhoids. It is very doubtful if scientific medicine is wanting in any of the appliances, which, taken alone, are the stock in trade of the exclusive practices.

The personal factor enters so largely into individual success in the practice of medicine, that the community judges of results mainly by its observations of the mode by which the results are obtained. The community is influenced less by a system of practice than by its confidence in the man in whom it has trusted. The community is as incompetent to decide upon the merits of the former as it is capable of being deceived by the skilful manipulation of the latter. This personal factor makes personal character take front rank in qualification for medical practice. The community may suffer seriously by its patronage of nostrums and exclusiveness, but the community undergoes greater peril and the *corps d'esprit* of the medical profession is outraged infinitely more by the incompetency to which it has given its diploma, and by the dishonesty and trickery in its ranks, which it sees and cannot control. Whoever can deny the one or the other is blind to human frailty, and he is to be credited with angelic confidence too pure and ethereal for this "vale of tears." The physicians who are floundering through the uncertainties that ignorance imposes, or who abuse the confidence of the community for purposes of gain; who will take any other course than to tell the truth and employ the most experienced devices to secure the speediest results, are beyond the reach of all codes, whether of human or archangelic contrivance. And yet the profession, in all consistency, having granted those the degree with a free heart and a God-speed, must consult with them on equal terms, and, in an emergency, defend them in the public confidence. To turn a child from the door as an outcast is inhuman.

[1] These figures are, doubtless, far below the actual facts. The census reports 563 patent medicine establishments, producing $14,682,494, and 8,592 drug and chemical establishments producing $38,173,658. Three times this amount, distributed through the 30,000 drug stores, would give an average total sales for each of $5,000.

THURSDAY, FEBRUARY 6TH, THIRD DAY.

MORNING SESSION.

DR. E. L. PARTRIDGE, of New York, read a paper on the

MANAGEMENT OF FACE PRESENTATIONS.

He said that the transformation into face presentations occurs within the last two weeks of pregnancy. He narrated a number of cases in which, under chloroform, he introduced the hand and converted a face into a vertex presentation. He proposed the questions: "Is it desirable to effect a change to vertex? and Is the operation easy and free from danger?" The favorable circumstances are: dilated os, a face easily lifted from the pelvic brim, unruptured membranes, and capacious vagina. The operation is easy, it being only necessary to introduce the finger into the uterus.

DR. A. JACOBI, of New York, read a paper on

ARSENIC AND DIGITALIS IN PHTHISIS.

He said that arsenic in small and frequent doses improves the connective tissue growth, which is probably due to the action on the cells themselves. Consumption is usually of long duration, and nutritive disorders are frequent. Arsenic is the best alterative and nutritive which we can employ. He does not use it while hectic fever is high, but when the temperature falls arsenic in small doses is a very valuable agent in doses of from one-fifteenth to one-sixth of a grain, with little opium. Digitalis is also valuable. Almost the universal method of use is a grain and a half of the extract combined with other remedies indicated; this may be continued for weeks. When there is no fever iron may be given. In anæmia, digitalis is an excellent tonic with iron, nux vomica, and arsenic.

DR. DRAKE agreed with Dr. Jacobi, but he thinks arsenic is more useful in the second stage. He uses it to reduce the temperature. Digitalis is used in Bellevue Hospital in almost all cases of pneumonia, and in all cases of alcoholic pneumonia.

DR. W. WOODWARD, of Big Flats, reported

TWO CASES OF POISONING BY TANSY.

Case I.—An unmarried girl, aged twenty-one, was seen September 21, 1879. She had been found in an outside cellar in an unconscious condition, having convulsions, and frothing at the mouth. She had never had fits before. The menses had stopped in the preceding February, and, from the enlargement of the abdomen, it was supposed that she had dropsy. She had been advised by a relative to take something to bring on the menses, and an examination of the drug taken showed it to be oil of tansy. On examination, the abdominal enlargement was found to be due to pregnancy. She recovered from the effects of the drug, and in the following December was delivered of a child said to have been stillborn.

Case II.—Mrs. W. G., aged twenty-nine, was seen June 16, 1882. In the early part of the morning, she appeared to be perfectly well, but about nine o'clock she felt dizzy, became partially blind, and passed into an unconscious condition in which she remained for an hour, when she partially recovered, and sent for assistance. At two o'clock P. M., the temperature was 100°, the pulse 80 per minute, and the respiration slow, but not stertorous. She could speak in a whisper, and could see large objects, but was unable to recognize individuals. She became faint whenever the head was raised from the pillow. On questioning her, it was found that for the preceding three days she had been drinking an infusion of tansy, and injecting the same into the vagina with the intention of producing abortion, being so engaged when she first fell on the floor. A vaginal examination showed the os uteri closed, and the lips patulous and soft.

About nine A. M. of the 17th, she became convulsed with clonic spasms, and lost consciousness. There was a second attack at three P. M. From four to five P. M., there were partial loss of consciousness, blindness, and slow respiration (fifteen per minute). It was said that during the paroxysm the respirations were stertorous. The pulse was slow or normal, and there was no disturbance of the bowels or of the urinary apparatus. Not receiving encouragement in her efforts to produce abortion, she consulted another physician. Shortly afterwards she had a miscarriage.

THE NOMINATING COMMITTEE

then presented the following report, which was adopted:

President.—Dr. B. F. Sherman, of Ogdensburgh.

Secretary.—Dr. William M. Smith, of Syracuse.

Treasurer.—Dr. Charles H. Porter, of Albany.

Censors.—Southern District: Drs. F. A. Castle, Geo. H. Fox, D. Webster. *Eastern District:* Drs. E. D. Fergusson, N. L. Snow, LeRoy McLean. *Middle District:* Drs. A. Churchill, J. K. Chamberlayne, Frazer. *Western District:* Drs. T. F. Rochester, B. L. Hovey, T. Dimon.

Committee on Ethics.—Drs. A. Jacobi, A. Matthewson, C. E. Whitbeck.

Honorary Member.—Dr. Wm. G. Bronson, of Connecticut.

Adjourned.

NEWS ITEMS.

ALBANY.

By Telegraph to our Special Correspondent.

THE NEW STATE MEDICAL SOCIETY.—On Wednesday morning a meeting of the adherents of the National Code of Ethics was held at the Delavan House, and the New York State Medical Association was organized. The following officers were elected:

President.—H. D. Didama, M.D., of Syracuse.

Secretary.—E. D. Ferguson, M.D., of Troy.

Treasurer.—John H. Hinton, M.D., of New York.

Dr. Austin Flint, Jr., proposed New York as the next place of meeting, which was adopted. It was resolved that the time of meeting should be the third Tuesday of November.

GASTROSTOMY.—On Thursday of last week, Dr. S. W. Gross, at the Jefferson Medical College Hospital, performed the first stage of the operation of gastrostomy on a woman aged fifty-one, suffering from carcinoma of the œsophagus. On the eighth day the woman's temperature and pulse were normal, and the case was progressing most favorably.

A BILL TO PREPARE AND PUBLISH A NATIONAL PHARMACOPŒIA FOR THE UNITED STATES.—In the House of Representatives, on January 8, 1884, Mr. Randall introduced the following bill, which was read twice, referred to the Committee on Ways and Means, and ordered to be printed.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,

That the Secretary of the Treasury shall, as soon as practicable, detail two officers of the Marine-Hospital Service, and the Secretary of War shall detail two officers of the Medical Staff of the Army, and the Secretary of the Navy shall detail two officers of the Medical Staff of the Navy, for the duty of compiling and preparing a pharmacopœia, which shall be known as the *National Pharmacopœia of the United States of America*, and shall

be held and accepted as the standard for the purveying, compounding, and dispensing of drugs or medicinal agents, and shall be taken as authority in the Treasury Department on all questions arising under the tariff laws of the United States with regard to the nomenclature, description, and purity of drugs or remedial agents, and shall further be received as evidence in the United States courts. And the matters contained in the said pharmacopœia shall be free for use by all authors and commentators for the benefit of the medical and pharmaceutical professions and of the community at large; and it shall not be lawful for any one to reprint and publish the said pharmacopœia as a whole.

Sect. II. That the medical officers detailed as above provided shall invite the American Medical Association and the American Pharmaceutical Association, at their next annual meetings, to form committees of not more than three members from each of the said Associations, which committees, if so appointed, may coöperate with the above-named medical officers in the preparation of the said pharmacopœia, forming a board which shall have power from time to time to add to its number as may in its judgment be necessary, and which shall elect a chairman and a secretary, and adopt such rules as it shall see fit for the expediting and perfecting of the said pharmacopœia, which, when completed, shall be printed under the supervision of the said board; and an edition of not less than five thousand copies shall be printed, for use in the several Departments of the Government of the United States; and copies may be furnished to private persons in accordance with the provisions of section thirty-eight hundred and nine of the Revised Statutes.

Sect. III. That for the purpose of defraying the necessary expenses of preparing the said pharmacopœia, the sum of five thousand dollars is hereby appropriated out of any moneys in the Treasury not otherwise appropriated, and the same shall be disbursed under regulations to be prescribed by the Secretary of the Treasury.

Sect. IV. That the said pharmacopœia shall be revised once in ten years, upon the plan embodied in this Act.

PRECAUTIONS AGAINST YELLOW FEVER.—The Secretary of the Treasury has approved the recommendation of Surgeon-General Hamilton, that an immediate inspection be made of the cities bordering on the Gulf of Mexico and the Caribbean Sea, having commerce with the United States, in order that their actual sanitary condition may be known in advance of the yellow-fever season.

THE ALUMNI OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK had their annual dinner on the evening of January 31, at Delmonico's. Dr. Alexander E. McDonald presided. Speeches were made by Drs. Fordyce Barker, S. O. Van der Poel, and others, in response to toasts.

THE DEPARTMENT OF VETERINARY MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.—We are informed that the organization of this department of the University of Pennsylvania has been completed, and the members of the faculty, with the exception of two or three special teachers, appointed. The faculty includes William Pepper, M.D., LL.D., Provost of the University and *ex-officio* President; Rush Duffen Huidekoper, M.D., V.S., Dean, Professor of Internal Pathology, and *pro tempore* Professor of Veterinary Anatomy; James Tyson, M.D., Professor of General Pathology and Morbid Anatomy; Horatio C. Wood, M.D., LL.D., Professor of Materia Medica, Pharmacy, and General Therapeutics; Theodore G. Wormley, M.D., LL.D., Professor of Chemistry and Toxicology; Harrison Allen, M.D., Professor of Physiology; Joseph T. Rothrock, M.D., B.S., Professor of Botany; Andrew J. Parker, M.D., Ph.D., Professor of Comparative Anatomy and Zoölogy; Robert Meade Smith, M.D., Professor of Comparative Physiology; —— ——, Professor of Surgical Pathology and Obstetrics; Adolph W. Miller, M.D., Ph.D., Demonstrator of Pharmacy; Henry F. Formad, M.D., B.S., Demonstrator of Pathology and Morbid Anatomy.

The course of study extends over three years, the year beginning October 1 and ending on June 15. The requirements for admission to this department are the same as for the Department of Medicine. The studies are for—

First Year.—Chemistry, Materia Medica and Pharmacy, Physiology, Histology, Botany, Zoölogy, Veterinary Anatomy, and Forging.

Second Year.—Medical Chemistry, Physiology, Therapeutics, General Pathology and Morbid Anatomy, Veterinary Anatomy, Surgical Pathology, Internal Pathology and the Contagious Diseases, Botany, and Zoölogy.

Third Year.—Therapeutics, General Pathology and Morbid Anatomy, Surgical Pathology and Operative Surgery, Internal Pathology and the Contagious Diseases, Sanitary Police, Obstetrics, and Zoötechnics.

In the second year the student will attend clinics, and will serve as aid in the hospital; in the third year, he will be placed in charge of sick animals, and be required to prepare clinical reports and make autopsies. He will also make regular visits to breeding and dairy farms and to slaughter-houses, in order to familiarize himself with the races of animals, the economical means employed in their care, and the varieties of butcher-meat.

Examinations will be held at the close of each year and at the end of the course. All these examinations must be passed satisfactorily before the student can be registered as a candidate for the degree.

Graduation.—Upon completing satisfactorily the full course of study, the student receives the degree of Veterinary Surgeon (V.S.), upon the same conditions as those on which the degree of Doctor of Medicine is conferred.

A handsome amphitheatre and large rooms for dissection and laboratory work have been erected, and the stables requisite for hospital use will be finished and occupied before the opening of the department, in September, 1884.

THE NEW YORK POLYCLINIC.—The faculty of the New York Polyclinic, recognizing in the increased prosperity of this institution the necessity for further effort in the direction of post-graduate study for practitioners of medicine, have determined to enlarge, to some extent, the scope of their work, and to provide more commodious lecture-rooms for their classes.

To this end the management have purchased the extensive property heretofore in part occupied by the Polyclinic, which, already well adapted to purposes of

medical instruction, will be remodelled and fitted out with comfortable amphitheatres for clinical work, well-furnished laboratories for chemical, histological, and pathological studies, and rooms for operative surgery and demonstrations in surgical anatomy. Two hospital wards will be set aside for the accommodation of such typical cases of injury and disease as may be instructive to the classes and elsewhere with difficulty observed.

THE PHILADELPHIA CLINICAL SOCIETY.—The Northern Medical Association of Philadelphia reorganized at the College of Physicians on the evening of January 26th, as the Philadelphia Clinical Society. A large number of new members were enrolled, and the following officers elected for the ensuing year:

President.—Henry Beates, Jr., M.D.
First Vice-President.—E. E. Montgomery, M.D.
Second Vice-President.—Hannah T. Croasdale, M.D.
Corresponding Secretary.—J. E. Richardson, M.D.
Recording Secretary.—J. G. Heilman, M.D.
Reporting Secretary.—G. Betton Massey, M.D.
Treasurer.—L. Brewer Hall, M.D.
Censors.—A. S. Barton, M.D., S. N. Troth, M.D., Albert H. Smith, M.D., James B. Walker, M.D., and Henry Rihl, M.D.

TRAINED NURSES IN ROME.—One of the newest fields of activity for the graduates of the Bellevue Training School for Nurses, according to the *New York Tribune*, is Rome. The Rev. Dr. Nevin, Rector of the American Episcopal Church, organized the movement in response to the solicitations of travellers exposed to the insidious fevers of the Campagna, and subjected to the ignorance and inexperience of Italian nurses. His idea was that there were a sufficient number of American and English invalids in Rome and adjacent cities to give constant employment to an organized association of trained nurses. Having formed his project, he sent to the Bellevue Training School for recruits. It is very satisfactory to learn that these volunteers have succeeded admirably in their work. The agency is known as St. Paul's House for Trained Nurses, with an office at No. 16 Via Palermo, Rome. The manager, Miss Adelaide S. Martin, supplies nurses for cases of sickness anywhere in Italy. During the first ten months forty-eight applications were received and twenty-three cases treated. The number of nurses will be doubled during the present season, and there is every prospect that the association will speedily become self-supporting. A majority of the nurses employed are Americans, and their efficiency in the sick-room, their self-possession, and quiet ways are generally commended. They are doing excellent work, and are adding steadily to the reputation of the institution at home which gave them their scientific training.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending January 26, 1884, indicate that influenza, rheumatism, tonsillitis, typho-malarial fever, and cerebro-spinal meningitis have increased, and that remittent fever has decreased in area of prevalence. Including reports by regular observers and others, diphtheria was reported present during the week ending January 26, and since, at twelve places, scarlet fever at twelve places, and measles at eight places.

OBITUARY RECORD.—DR. ELISHA HARRIS, Secretary of the New York State Board of Health, died of peritonitis, in Albany, on Thursday, January 31. Dr. Harris was born in Westminister, Vt., in March, 1824. He received his medical education at the College of Physicians and Surgeons, New York City, receiving his degree in 1849. During the civil war, he took an active part in the improvement of the United States Sanitary Service, and invented a railway ambulance, which received a prize at the Paris Exposition in 1867. Dr. Harris was a large contributor to medical and sanitary literature.

NOTES AND QUERIES.

RADICAL CURE OF ARTIFICIAL ANUS.

To the Editor of THE MEDICAL NEWS.

SIR: I note, in THE MEDICAL NEWS of this date, the editorial remarks upon the subject of "The Radical Cure of Artificial Anus," in which you kindly alluded to my case published in THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, in 1867. You say that, "although the operation failed, to Dr. Kinloch belongs the credit of having been the first to practise enterectomy and enterorrhaphy for the lesion under consideration." But should not the word *failed* be qualified in some way, even if it is correct to use it in connection with my operation? To me the *success* of the operation was more gratifying than any that has before or since followed upon a surgical procedure. The operation saved my patient's life when death was regarded as most imminent. It reëstablished the track of the intestinal canal, and the natural flow of its contents; and there followed immediately such improvement in the nutrition of my patient that in a remarkably short period of time he weighed over two hundred pounds, and again pursusd his accustomed occupation in life. The "failure" then consisted merely in the fact that through the giving way of a suture a slight fistule was left, which discharged a little serous liquid up to the time when I lost sight of the man.

The suggestion for such an operation, which you say was made by "the elder Gross, thirty-seven years ago," I was not aware of at the time.

Very truly yours,

R. A. KINLOCH, M.D.

CHARLESTON, S. C., February 2, 1884.

RUPTURING THE MEMBRANES IN LABOR.

To the Editor of THE MEDICAL NEWS.

SIR: I have been engaged in the practice of medicine for twenty years, and have been a constant subscriber and reader of THE MEDICAL NEWS and THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES since 1865, and, during these years, have *read* of many ways of rupturing the amniotic membranes; but have yet to see the first case in which the "Amniotome" or any other "*tome*" was needed, save the one that God gave us—the index finger. It is plain to my mind that the membranes are ruptured early in labor for the benefit of the doctor more than the patient.

I have been, in several cases (years ago), quite anxious about the fœtus, for fear it would be "drowned in the waters." But I have yet to meet with any ill consequences from allowing the membranes to proceed entire until I could *pinch* them open with my *thumb* and *forefinger*.

Of course, this shuts out the "embellishments of the profession," especially "*Amniontomes*," and entitles me to the distinction of an "old fogy." Yet I do not believe that God ever intended, or the welfare of the patient ever demanded the rupture of the membranes until labor had so far advanced that it could be accomplished without the aid of instruments; save those that God has given us.

Respectfully,

S. E. HAMPTON, M.D.

MILTON, KENTUCKY, January 22, 1884.

THE MEDICAL NEWS will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—
[illegible] not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ANOMALOUS DISLOCATION AT THE HIP-JOINT OCCURRING DURING PARTURITION.

A Clinical Lecture.

BY STEPHEN SMITH, A.M., M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY MEDICAL COLLEGE, NEW YORK.

GENTLEMEN: The subject for examination and study to-day has a twofold interest, viz.: 1. The form of dislocation of the femur at the hip-joint is anomalous. 2. The cause of the dislocation is unusual. Both of these facts will be apparent on reciting the history of the case as it has been given me, and on examining the present position and condition of the limb.

The patient is about thirty years old, mother of three children, short of stature, and strongly built. She states that when about to be confined of her second child, she called her medical attendant on the occurrence of the first pains. He expressed great desire to have her labor expedited in order to relieve him, that he might attend another case. Accordingly, he ruptured the membranes, and encouraged her to force her pains. The labor became very active, the child advanced rapidly, and during the pains he threw his whole weight upon the right thigh, which was strongly flexed upon the body, and the leg upon the thigh. The accoucheur was a large and powerful man, and, during the expulsive stage, she recollects to have suffered from the force he exerted upon the thigh in counteracting her efforts, and the extreme flexion to which the thigh was subjected.

After the labor she experienced only the usual soreness of the limbs consequent upon such muscular efforts, and she continued to do well until the fourth day, when she sat up in bed. While attempting to leave the bed on the eighth day, she was seized with violent pain in the right thigh and leg. It extended to the ankle at first, but finally became fixed in the thigh and knee.

At an early period the foot began to be everted, and the leg flexed upon the thigh. The eversion of the foot gradually increased, and the pain was so great that she had to be relieved by hypodermic injections of morphine. She could not from the first move the limb, or sit up straight in bed. She continued to be confined to her bed for three months, and several times a day received the morphine injections for the relief of her pain.

After this time she began to be removed from her bed, and made every possible effort to walk and move around her house. The most noticeable features of her case, as she describes it, after she began to walk about the house were, eversion of the foot to a right angle, a hollow on the posterior part of the hip over the joint, and a movable, hard tumor anterior to the joint.

Three years have now elapsed since the accident from which she dates her troubles. Mean time, she has been once confined, and is again far advanced in pregnancy.

We will now examine the limb carefully, and determine, as far as possible, what is the nature of the deformity. And first, we should learn as much as possible by inspection, before we attempt manipulation. As she lies on the table, the right leg appears markedly shortened; the foot is not only turned outward, but actually lies on its external margin; the patient has lost the power of inverting it. On placing her upon her feet, the deformity appears more marked. The right leg is now apparently very much shortened; the foot is naturally placed at right angles with the other, the heel of the right opposing the arch of the left. When she walks there is no change in the relations of the feet, and the difference in the length of the limbs becomes more apparent by the painful limp which is developed.

On placing her again in the recumbent position, for manipulation of the limb, we find the most marked feature of flexion to be the development of a movable tumor, just below and rather internal to the anterior superior spinous process of the ilium. On grasping this tumor, it is found to be hard, round, about the size of a small orange, and movable only when the limb is rotated. On more careful manipulation, it is perfectly evident that this mass is the head of the thigh-bone—displaced to this unusual position. Measurements can now be made to verify the diagnosis, and determine the amount of shortening. Placing the left limb as nearly as possible in the position of the right—for, as you can see, the left cannot be made to assume the same exact position—we first measure from the anterior superior spines to the tip of the internal malleoli, and find a difference in favor of the left limb of two inches and a half. There is, then, very marked shortening of the right limb, as regards its relation to the joint. But there is another measurement which we can make to determine whether the entire length of the right limb—regarding this tumor as the head of the femur—is shortened. I can just distinguish the upper extremity of the trochanter major on the right side, and taking this projection as the upper point on the two sides, I find no very perceptible difference in the length of the two limbs.

Grasping the tumor firmly when she steps, it is found that it descends markedly when she raises her foot, and then ascends as she brings her weight to bear upon the limb. In fact, when she stands upon the right leg, the tumor becomes very prominent and well defined as the head of the femur. The conclusion at which I arrive is this, viz., the patient is now suffering from an old luxation of the head of the femur from the hip-joint, the displacement being in the anomalous position under the anterior superior spine of the ilium. At that point where the curve of the ilium gives some support to the head, a new joint forms, which in time serves a very good purpose in the ordinary anomalous dislocation. New bone arches over and around the head, especially on the

upper and posterior portions, and a cup-shaped cavity results, having the appearance and functions of the original acetabulum. In this case, however, it is doubtful if any such rudimentary joint will, or indeed can form, owing to the absence of a bony surface on which the head of the bone can rest.

The question of treatment can be readily answered. Replacement is impossible in her case. No form of operation can give useful results. There is but one method of relieving her disabilities, and that is by the use of the ordinary hip-splint. The value of this splint to her would be that it would enable her to walk upright, and the weight of the body would be transferred from the leg to the splint. Locomotion would then be comparatively easy, and eventually a new joint might be formed at the lower point where the head would rest on the pubic bone.

Let us now consider briefly the more unusual features of the case. First. Could the dislocation occur from the alleged cause, viz., extreme flexion of the thigh by the accoucheur, and forcible resistance on the part of the patient? It will readily be seen that in this position of the thigh, with the degree of abduction which necessarily follows, the head of the bone is brought into a position in the acetabulum where the cavity is most shallow, and resistance to its escape is at a minimum. It does not seem improbable that during the last stage of parturition the head of the bone may have been so far forced from the socket as to have ruptured the capsule. The nearest approach to this case is that of a person who is reported to have dislocated the femur upon the pubis in the act of "striking out" while swimming. The position and forces in the two cases were not unlike, except that in the case before us there was added the pressure of the accoucheur upon the extremely flexed thigh. It is, I think, proper to assume that this dislocation did occur at the time and in the manner alleged. If this is true, another question arises, viz., Did complete dislocation occur during labor? She alleges that she had only the usual soreness and stiffness which follow labor, and it was not until she attempted to leave the bed that she was seized with severe pain. We may account for these symptoms by supposing that the head was lodged on the pubic bone just without the acetabulum, where it remained without causing any such marked symptoms as to excite attention. When, however, she began to move in the effort to get out of bed, the head of the bone was further displaced upwards and inwards, and by its pressure upon the nerves, gave rise to the severe pains which she afterward suffered. The parallel of this condition is found in the case of the man who dislocated his thigh-bone upon the pubic bone while in the act of swimming. All the inconvenience he suffered at the moment was "a catch in the right groin, which he thought was a cramp," and he was able "to walk after the accident, but with a good deal of difficulty." The position of the head of the bone is such as to lead to the classification of this dislocation among those described as "anomalous." In this form the head of the femur is usually located external to the anterior inferior spinous process, and below the superior process. It may, however, have other positions in that vicinity and still belong to the class of dislocations known as "anomalous," or by some writers as the sixth form of dislocation at the hip-joint. In this case the head is between the two spinous processes and anterior to them, and in this respect is one of the more rare forms of anomalous dislocation.

ORIGINAL ARTICLES.

A YEAR'S WORK IN OVARIOTOMY.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF CLINICAL GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

DURING the past year I have performed, as the subjoined table will show, twenty-five cases of completed ovariotomy, with seven deaths. Besides these, I had one, a patient of Dr. E. W. Watson, in which the operation was not completed. The cyst was fastened to every structure it touched, and, after the upper adhesions were severed, it was found to spring from a cancerous mass involving all of the pelvic organs. No further effort to remove it being warrantable, a drainage-tube was put in; but the patient died a few days later.

Of the twenty-five cases of completed ovariotomy, four were performed at my private hospital, with one death, which was caused by the bursting of a pelvic abscess into the bladder. Eleven were operated on in the Hospital of the University of Pennsylvania—which is a public hospital—with only one death, and that one from hospitalism. Ten were operated on at their own homes, with five deaths. Of these five fatal cases, I did not again see but one of them after the operation, and she died in eight hours, from the shock of the removal of an intraligamentous and purulent cyst.

I am always sorry not to have the subsequent management of my ovariotomy patients, but this is not always possible. Our countrywomen are very averse, not only to being operated on, but also to being operated on away from home. Hence their unwillingness to go to hospitals, and their proneness to delay matters until they have become too weak to travel. Again, three of the seven fatal cases were at the time of the operation very ill from septic fever caused by purulent cysts. In two, the cyst-walls had broken down from previous tappings, and this is another grave fault of our women, who insist on being tapped, and who put off the operation until the cyst has become very large, or has contracted adhesions. Thus, out of the twenty-five cases, there were only eight without adhesions. While my statistics do not make as good a showing as those of British ovariotomists, there is this to be said in my favor—that I have never refused to operate on a woman however slim her chance of recovery. I make this statement because, according to Sutton,[1] Billroth is the only one among European operators who "refuses to operate upon nothing that deserves the chance of life," and his success amounts to about sixty-five per cent.; whilst a very distinguished and successful British ovariotomist "does not remove very large tumors—those which weigh from sixty to sixty-five pounds, with extensive adhesions, etc."

The history of the fatal cases is as follows:

Case 93 was operated on at my private hospital, April 28th, in the presence of her family physician, Dr. G. R. Robbins, of Hamilton Square, N. J. The operation was not a difficult one, although the lower portion of the cyst had to be enucleated from the broad ligament. Everything went on smoothly for several days, then a pelvic abscess formed, and burst into the bladder, ending in the woman's death on the eleventh day. She was a sister to a lady from whom I had successfully removed both ovaries—viz., Case 77 of my series published a year ago in this Journal.

In Case 96 the tumor had existed and caused much suffering for six years. In the last year it gave rise to such desperate and stubborn attacks of vomiting that her physician, Dr. W. J. Keath, of Schaefferstown, Pa., despaired of her recovery. Three times, to save her life, he tapped her, removing on each occasion about twenty pounds of fluid. Until her health had wholly broken down, and she was convinced that nothing else would do, she would not listen to having the radical operation performed. I saw her for the first time on June 16th, the day of the operation, which was performed at her home in Lebanon County. My assistants were Drs. J. R. Bucher, John Bucher, and Reincehl, of Lebanon, and Dr. W. J. Keath, of Schaefferstown, Pa. The contents of the cyst were purulent, and, as far as I could make out, it was a thick-walled intraligamentous cyst of the left ovary, adherent at every point to the abdominal wall, intestines, womb, and pelvic tissues. The corresponding cornu of the womb had to be transfixed and tied for a pedicle. The right cyst was also much enlarged by a cluster of cysts containing a brown plaster-like material, and it was also adherent at every point. I did not see her again, but Dr. Keath wrote me that, directly after she had rallied, vomiting set in, and kept up until the sixth day, when she died.

Case 97, operated on at her home in Scranton, Pa., died on the ninth day from some obscure cerebral lesion. There were delirium and other head-symptoms, but no tympanitis, abdominal tenderness, or other signs of peritonitis. The operation was not a difficult one, but both ovaries were removed, and the woman was fat. I did not see her afterwards, and her physician was also called away on the fourth day, when she appeared to be doing well.

In Case 102 the tumor had been discovered a year before I saw the patient. As it developed, she suffered more and more from abdominal pains, chills, and fever, and became bedridden. After getting no better from a homœopathic treatment of several weeks' duration, she was sent to Atlantic City, where I saw her August 1st. She was bedfast from severe pain, septic fever, vomiting, night-sweats, and great prostration. Her temperature was high, and her pulse frequent. As she was not in a fit condition for the radical operation, and as she needed closer attention than I was willing to give her during my vacation, Dr. Boardman Reed kindly took charge of her, and on the 3d inst. we aspirated the cyst. The contents, amounting to about five quarts, were purulent, and their removal was followed by temporary relief from some of her symptoms. After two weeks, she was able to sit up for a few minutes, but the sac soon refilled, and the former train of symptoms started afresh. In order to get her into a fit condition for the radical operation, on September 2d I again aspirated. The fluid removed was now wholly pus. She was less relieved by this operation than by the former, and her pulse never fell below 120 beats. On September 14, aided by Drs. B. F. Baer and William L. Taylor, and by my son, I removed the cyst at her own house. As far as I could make out, it was an intraligamentous cyst—viz., one which had developed between the two layers of the broad ligament, but of this I am not sure, as all landmarks were obliterated. At any rate, the cyst was adherent and enveloped everywhere. The bladder lay in front, reaching nearly to the navel, and was so closely incorporated with the cyst-wall as to need very careful dissection. The tumor was then enucleated from its pelvic envelopes, and removed without a pedicle. A number of vessels had to be tied, but she lost very little blood. A drainage-tube was put in. She died from shock eight hours afterwards. On reviewing this case, I think that, in lieu of removing the cyst, it would perhaps have been better simply to have emptied it, and put in two drainage-tubes.

Case 104 was also operated on at home. I did not see the woman after the operation, in which I was assisted by Drs. H. St. Clair Ash, E. L. Duer, and B. F. Baer. There were very firm pelvic and uterine adhesions. By the latter the womb had been greatly lengthened out, and the vagina so stretched that the cervix uteri was effaced. The woman was extremely despondent about herself before and after the operation. On the fourth day, symptoms of intestinal obstruction set in, which could not be overcome, and from which she died on the eighth day.

Case 108 was another forlorn hope, from blood-poisoning before the operation. She was tapped by her physician on October 8th, and again on November 10th. At the latter operation, as the fluid was supposed to be ascitic, and upon its withdrawal a cyst as large as the adult head was found, a hypodermic syringe was plunged into it and fluid enough for a microscopical examination sucked out. The result was an alarming peritonitis which demanded prompt treatment. I saw her at her home for the first and last time on December 1st. She was bedfast, very weak, greatly emaciated, and unable to lie on her back. She had night-sweats and a frequent pulse. The tumor consisted of one large cyst, filled with pus and broken-down flakes of lymph, and a nearly solid portion as large as the adult head. The adhesions were absolutely universal. The bowels lay behind, matted together by thick layers of dirty lymph. Every abdominal organ was plastered over with this lymph, from which protruded many bladders or blisters of serum. Very few ligatures were needed, but a drainage-tube was put in. She died twelve hours later, either from shock, or, as her physician thought, from internal hemorrhage.

In Case 110 both ovaries were removed, and the larger one had many parietal adhesions, needing a few ligatures. The case was a promising one, yet the woman died on the fourth day from peritonitis. I believe that hospitalism was at the bottom of this result, for she was operated on in the Hospital of the University of Pennsylvania, which is a general hospital, receiving many railroad accidents. Further, her room was opposite and very near to the door of the general female ward, where several suppurating wounds were dressed daily. I relied too much on the antiseptic precautions employed, and, perhaps, also on the good record of the ovariotomies which I had performed in the same building during the eleven previous months. These were ten in number, and all of them successful. They were all operated upon in private rooms, at a distance from the wards, but under the same roof, and were kept out of the wards until all danger was passed. In this instance, however, as the distant rooms were occupied, my patient was placed in a room directly opposite to the entrance of the female surgical ward.

Out of the twenty-five cases, there were twelve of double ovariotomy, with four deaths. In all these cases the second ovary was positively diseased. Yet, with a larger experience, I am, under certain conditions, becoming more and more in favor of removing both ovaries. Whenever both ovaries are diseased, there can be no question about their extirpation; but when only one has undergone cystic or other degeneration, the removal also of the sound one may, under certain circumstances, be good policy. There always is a tendency to the subsequent degeneration of the sound ovary after the diseased one has been removed. More especially is this tendency observed in sterile women, and in those with malignant affections of the ovary. Hence many women whose lives should have been imperilled but once, have undergone the dangers of a second operation. In view of these facts, it seems to me wise to remove the sound ovary in some cases of sterility, in every case of malignant degeneration of one ovary, and in all women who either have passed the climacteric or are approaching it. I should also remove both ovaries in cases complicated with fibroid tumor of the womb. In these convictions I am further strengthened by the disappointment often expressed to me by my patients that both ovaries had not been removed, for they had a morbid dread of the remaining ovary taking on cystic degeneration.

Out of these twenty-five cases, there were only eight without adhesions, and one of these died. In four the adhesions were universal, and three died, two of them from shock. In the one that recovered, oozing from the denuded intestines was stopped by the actual cautery at a black heat. In four the adhesions were very formidable, being either uterine or vesical. Of these, one died. Case 87 had very firm uterine, vesical, and pelvic adhesions. Troublesome oozing came from the surface of the bladder and womb, which, hot water failing, was stopped by Monsel's solution applied by a sponge; the convalescence was uninterrupted. Case 95 was, as shown by microscopic examination, a spindle-celled sarcoma. Firm adhesions to omentum, bladder, and intestines needed many ligatures. The omentum was also greatly thickened and hypertrophied. The woman recovered, and is now well; but I look for an early return of the disease, for, in an analogous case, No. 65 of my published series, in which I operated February 14, 1882, the patient remained well for several months, then a tumor developed, and she died eleven months afterwards. In Cases 90 and 100, the tumors were also probably malignant. The former had been tapped fourteen times for ascitic fluid The tumor proved to be a small, solid, and nodulous growth of the ovary. It was not examined microscopically, but looked very suspicious; thus far the woman remains well.

In Case 100, the parietal and visceral peritoneum was studded with small, hard nodules, and there was much ascitic fluid. Owing to intestinal obstruction in the third week, the patient had a desperate struggle for life; but, when everything else failed, thanks to ten-drop doses of belladonna administered every two hours, the bowels were finally opened. The patient slowly convalesced, and got very well; but her physician, Dr. T. West, of Keyser, West Virginia, thinks that fluid is again collecting in the abdominal cavity, and that growths are forming at the site of each pedicle.

It is surprising what a large percentage of ovarian

tumors turn out to be malignant. The subsequent history often shows that cysts which present a perfectly innocent appearance to the eye at the time of the operation are in fact malignant. The patient recovers promptly from the operation, but dies a few months later from cancer of the pedicle, of the peritoneum, or of other organs. I have seen this happen several times. In my first case of ovariotomy, one in which the clamp was used, menstrual fluid for several months poured out from the cicatrix, which, in less than a year, became affected with cancer. Sometimes the diagnosis of malignancy can be made beforehand, but unfortunately very rarely.

From the marvellous changes often produced progressively in the epithelial lining of ovarian cysts, by which they are transformed into tufts of villous cancer, Tait inclines to the opinion that their growth is associated with a tendency to malignancy. He believes that tapping hastens this degeneration, and that after an accidental rupture of such a cyst the peritoneum will be studded with patches of papillary cancer. Hence he argues that ovarian cysts should never be tapped, and that they should be removed in the early stages of their existence before these malignant transformations have taken place.[1]

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.[2]

BY FORDYCE BARKER, M.D., LL.D.

IN the paper which we are now to discuss, the author distinctly avows his belief, without any qualification, that "puerperal fever is puerperal septicæmia," and that "it matters not whether it assume the form of metritis, phlebitis, cellulitis, peritonitis, or lymphangitis, the essence of the disorder is a poison, which is absorbed into the blood of the parturient woman through some solution of continuity." Not only the sentence quoted, but the whole tenor of the paper must convey to the unbiased mind that it is the well-defined opinion of the author that metritis, phlebitis, peritonitis, and cellulitis are never seen in the puerperal woman except as the result of an initial lesion, which permits the absorption of a specific poison through the parturient canal, either from the atmosphere—or from direct infection by doctors or nurses from neglect or carelessness—or other agents brought in contact with the sexual organs.

The tendency to this pathological view has been rapidly growing within the past few years, as a result of the enthusiastic interest excited chiefly by the important investigations of our German coworkers, who have so zealously studied the character and effects of the micro-organisms in puerperal women *in hospitals*. In several of the most recent and the most excellent systematic works on obstetrics, I have observed that nothing is said of the various local phlegmasiæ which are liable to arise in puerperal women as a consequence of parturition, and that they are only alluded to in connection with the subject of septicæmia. This seems to me a very grave omission, which must seriously embarrass young obstetricians, who consult these works for information when normal convalescence is interrupted by any of the local inflammations. No one, as yet, has maintained that the process of parturition and the puerperal state exempt a woman from those causes which induce local inflammation in the non-puerperal, or will deny that the process of parturition, and other attendant conditions besides the absorption of septic poison, may be the efficient cause of local inflammation; and I here state my conviction that in private practice, when there is no epidemic influence, twenty cases of local inflammation, due to such causes, will be met with where one will be found due to septic absorption.

It is hardly necessary to say—as I have before expressed the same opinions in a work published some years ago—that I am entirely in accord with the author in his preliminary remarks as to the peculiarities in the system of puerperal women. I suppose that all educated men now know that the blood of a pregnant woman is in a state of hyperinosis, and that, as a rule, "her nervous system is in a plus state of sensitiveness and excitability, and influences which are very controllable in the non-puerperal state produce very evil results here." But it is very evident that in certain points our opinions are wide apart. He regards certain conditions, which always are found following normal labor, and always occur in normal puerperal convalescence, as pathological, but which I believe to be purely physiological.

The ancients believed in the poisonous nature of the menstrual fluid. Pliny described the menstrual fluid as a "fatal poison—which corrupts and decomposes urine, deprives seeds of their fecundity, destroys insects, blasts the garden flowers and grasses, and causes fruits to fall from their branches."

I had supposed this superstition to be extinct, until informed by a letter from my friend, Dr. Weir Mitchell, that he knew "old men who would not permit a woman to enter their wine-room, for fear that, if menstruating, it would injure their wines." He also informed me that "in Roquefort women are not allowed in their cheese cellars." I suppose the theory must be that menstrual bacteria will destroy the bouquet of the Roquefort cheese.

But on the evening of December 6, 1883, in this Academy of Medicine, I first heard the full evolution of this doctrine clearly enunciated. The lochia are described as an offensive fluid, made up of dead and decaying animal tissues, which poisons freshly made, unprotected wounds. I quote textually two paragraphs:

"In every case of child-bearing the endometrium is thus encumbered, and freed by a process of exfoliation and sloughing; in every case the cervix, vaginal mucous membrane, perineum, and vulva, are, in varying degrees, lacerated; and in every case the offensive fluid, called lochia, poisons these freshly made, unprotected wounds."

[1] Diseases of Ovaries, p. 148.

[2] Read before the New York Academy of Medicine, February 7, 1884, at the adjourned discussion of the paper on this subject by T. Gaillard Thomas, M.D., which was read before the Academy, December 6, 1883. See THE MEDICAL NEWS, December 15, 1883.

Again, the writer says: "Here we have a number of recent wounds constantly and unavoidably bathed with a fluid made up of dead and decaying animal tissue, in a woman whose blood and nerve states are, with reference to septic disease, like flax prepared for the spark, and who is exhausted by pain, anxiety, loss of blood, and deprivation of sleep."

Other quotations might be given, of a similar tenor; and the prophylactic measures which, he asserts, "should be adopted in all midwifery cases, whether they occur in hospital or in private practice," are based mainly on this theory.

Can it be true that the process necessary for the birth of the human race is always attended with the development of a deadly poison whose malignant effects must inevitably prevent the spontaneous and kindly healing of such little traumatisms as always result from the process, and that, therefore, it is the duty of the accoucheur to take preventive measures of the character proposed? Does every parturient women, in performing the function of maternity, like the scorpion, that carries in its tail an agent for suicide, if death is threatened by fire, physiologically generate an equally fatal poison in a corresponding locality, which the obstetrician must guard against by means that are most inconvenient, alarming, and not altogether free from danger?

I do not intend now to examine the question, which I have before discussed very thoroughly, and my views have long been published, whether there is not a distinct disease, most appropriately denominated puerperal fever, when, if there be any septicæmia, it must be a consequence of a primary disease, and not a cause. Nearly a hundred years ago the eminent obstetrician of London who succeeded Denman, Dr. John Clarke, wrote as follows in regard to puerperal fever: "Unfortunately, the uniformity of the disease was assumed, and each author erected his own experience into a standard, by which to judge of the descriptions and the practice of others." This observation, which I read early in my professional life, made a strong impression on mind. I trust that it will not be deemed egotistical if I say that it had great influence on my mind during the twenty-five years that I was engaged in teaching medical students, as I felt strongly the responsibility of the position, and that I should be culpably negligent in my duty if I simply gave the results of my own observations, or the opinions of a limited number of observers, or the theories of a few popular authorities, but that I was bound to give the sum of the knowledge which had become a part of the common stock of the profession. For reasons which will be obvious, I felt this more strongly in regard to puerperal fever than any other subject which I had to discuss either before medical students or in medical societies. More has been written on this than on any one disease. It has been a terribly fatal disease in lying-in hospitals in all the great cities where such hospitals are found. It has been fatal as an epidemic in rural districts, where, within a certain area, every woman in a sparsely settled population, who gives birth to a child, for a certain limited period is affected, and a large proportion die. I could refer to very many published reports of such epidemics which have occurred in villages and towns, where for twenty-five or thirty years previous not a single death had occurred in childbirth except from the casualties of labor, such as rupture of the uterus, hemorrhage, and convulsions.

All we know of any disease is derived from the study of its etiology, its clinical phenomena, and its anatomical lesions. The epidemic disease to which I have just referred differs in all characteristic points from what is known as septicæmia. It differs in its origin, its modes of attack, its symptoms, and its anatomical lesions. The symptoms are frequently manifested a day or two before or even during labor, even when the child is subsequently born alive. In septicæmia the symptoms are never observed before or during labor, except when the fœtus is putrid. The former disease, puerperal fever, originates from epidemic causes, and from contagion and infection. The latter, from nosocomial malaria, from autogenetic infection, and from direct inoculation. Can a woman after childbirth be exposed to the danger of receiving the poison which produces septicæmia in larger doses than when she has retained in her uterus a portion of putrid, decomposed placenta? Yet I do not believe there is a single person who has had considerable obstetric practice for twenty years who has not had more than once to remove portions of putrid placenta which has been retained for days, and the patient has had no disturbance of such severity that he would call it puerperal fever. In the *Texas Courier-Record of Medicine*, December, 1883, Dr. H. C. Ghent, of Belton, Texas, gives an amusing report of a case to which he was called three days after labor. She was attended during labor by an ignoramus, who appears to have used considerable force, and probably made some efforts to extract the after-birth. The patient, before he left, called his attention to something like a cord protruding from the vagina, which he said would, perhaps, come away by piecemeal. On his visit the next day, he at first said that the protrusion from the vagina was a false conception, but afterwards pronounced it a falling of the womb, which, after a considerable length of time, he succeeded in replacing, and had the anxious husband engaged for twelve hours in constructing an abdominal supporter. On the third day, Dr. Ghent removed a large portion of the placenta and membranes, a putrid mass, with a stench which "was about as much as an ordinary pair of olfactory nerves could well bear." The patient had a quick pulse and high temperature, but the constitutional disturbance was easily allayed, as it seems that a "few thorough washings with hot carbolized water" were all the treatment required.

Before leaving this part of the subject now under discussion, I shall briefly allude to one other point, which strikingly illustrates the difference between puerperal fever and septicæmia. I think there can be no doubt that the majority of the profession believe that all those causes of nosocomial malaria, such as aggregation, bad ventilation, contact with

septic material, etc., which have a tendency to induce septicæmia in surgical cases, have an equal tendency to develop the disease known as puerperal fever in women recently confined. But this does not prove that the diseases are identical, for I think there is abundant evidence that, while these causes are always requisite for the development of surgical septicæmia, puerperal fever may be very epidemic when these causes are wholly wanting.[1]

In the early months of 1873, puerperal fever prevailed in the best parts of the city, and in that class of society possessed of abundant means and living under as good sanitary conditions as are possible in any large city, to a degree and extent here unknown for the previous twenty-five years. The deaths from this disease in the hospitals, and in the wards of the city where the poor are aggregated, were much less than in many former years. In five of the best wards of the city, in which are the residences of a great proportion of those of wealth, and few of the class of dwellings known as tenement-houses, with a population of 307,046, there were 80 deaths from puerperal fever, while in the remaining wards of the city, with a population of 605,245, there were but 63 deaths. In other words, I may say that during this period, in those wards of the city where the causes of septicæmia must have existed in the greatest abundance, the mortality was nearly one-third less from puerperal fever, in proportion to the population, than in the best parts of the city, where these causes of septicæmia could have existed only in a very limited degree.

I have good cause to remember this epidemic, as the excessive work, mental strain, and loss of sleep which it brought upon me, as my medical friends know, affected my health to a degree that required nearly six years for perfect recovery. I saw ninety-five cases of this epidemic, of which there were nineteen deaths. Most of the latter I believe to have been fatal in their character from the history which I received, and I only saw them once. I had three cases in my private practice, one of which died. After this, most of the ladies whom I had engaged to attend, by my advice, went out of town for their confinement, and all these had normal convalescence.

From all these considerations, I think that if all the knowledge of this disease be derived from authors who have studied it in hospitals exclusively, it will be limited and one-sided, and the deductions, both as to its pathology and treatment, must in many instances be erroneous and unsafe. Especially must this be the case with those whose well-deserved eminence as operators compels them to be brought in frequent contact with surgical septicæmia, and to witness the terrible results which this produces after the most skilful performance of such operations as laparotomy and ovariotomy. Indeed, one can hardly understand how such a surgeon, who accepts the theory and believes in the necessity of such a prophylaxis and such treatment as are insisted upon in the paper under discussion, would ever dare to enter the room of a puerperal woman.

There are many other details in this connection which I am tempted to discuss, but these will doubtless receive due attention from the speakers who will follow me. I shall, therefore, content myself by expressing an opinion which will surprise many who have been carried along by the popular wave of the septic theory as the initial cause of most of the puerperal diseases. My conviction is strong, based partly on individual experience, but chiefly on a careful study of the clinical midwifery reports of private practice and all the literature of the subject in my possession—and this is very full as regards the English and French languages—that, outside of hospitals, less than two per cent. of the puerperal diseases, and not half of one per cent. of the deaths after childbirth, are due to septicæmia. There are no statistics of private practice which demonstrate the error of this opinion. The belief of the septicæmists that terrible dangers threaten every woman in childbirth is based wholly on theory. Because the maternal system has certain peculiarities differing from its normal condition—because the lochia is a poisonous fluid—and because there is always a certain amount of traumatic lesion in the parturient canal following parturition, every childbearing woman incurs a most hazardous risk. This is a blunt statement of the argument and its deductions.

I do not care to summon in support of the opinion that I have just expressed any higher authority, even if it were possible to do so, than the writer of the paper which we are now discussing, and from which I make the following quotations:

"And yet what are the usual results? Recovery, uniformly, I might say universally, unless some unusual occurrence manifests itself to prevent this happy consummation. Theorizing about the matter, one would suppose that the mortality resulting from such a state of things must be excessive." . . .

"And yet the facts are these: only about one or two in every one hundred parturient women ordinarily die when properly cared for during labor, even in public hospitals."

Now, if we recall the fact that a large proportion of deaths from childbirth result from the casualties of labor, such as convulsions, rupture of uterus, hemorrhage from placenta prævia, nervous shock, etc., it will be seen that the belief which I have expressed differs but slightly, if any, from his. I certainly find it much more agreeable to refer to our points of agreement than our points of difference.

The limit of time which, in justice to others who follow, I have allowed myself will permit but a very few remarks on "the prophylactic measures which should be adopted in all midwifery cases, whether they occur in hospital or in private practice," as the author of the paper distinctly avows. If "she who is about to bring forth" must "be treated as one about to go through the perils of a capital operation;" if all those preparations, so definitely enumerated, which gynecological surgeons insist upon previous to an ovariotomy or a laparotomy, are

[1] See Puerperal Diseases, by Fordyce Barker, M.D., Appendix, page 515.

necessary in ordinary labors; if the danger from childbearing be so great that a wise and prudent obstetrician is justified in subjecting his patient to the hazardous depression of intense anxiety and fearful doubt as to results, and in surrounding her with the vivid apprehension of her family, instead of stimulating and cheering her with the great happiness of maternity and the hope of increased interest and love from her husband; if all or even a considerable part of the details mentioned are necessary "to save thousands of lives which are now lost," and to spare "thousands of desolate households the sorrow of losing their female heads"—then it seems to me evident that the State should make childbearing a penal offence for all those families who do not have a sufficient annual income to make it possible to carry out all these requirements. Such a law could only be made effective by adopting the facetious suggestion which appeared in the *Medical Record* of January 19th, over the signature of Seth Hill, Stepney, Conn., making it compulsory for all women unable to carry out these requirements "to wear an antiseptic pad over the vulva from the inception of the catamenia until the menopause, to be non-removable without strict antiseptic precautions under the carbolic spray;" and, to secure this pad, it would be necessary that some State official should apply the lock, which, no doubt, many present have seen in the Museum de l'Hotel de Cluny, said to have been used by the noblemen of France to prevent their wives from falling during their absence in the Crusades.

The description given of puerperal fever, true as it may be, in its outlines, of the septicæmia which gynecological surgeons are so often forced to encounter, I think, will strike obstetricians familiar with the disease in the lying-in chamber as the ideal picture of a poet, differing as much from the scientific description of trained clinical observation as the pictures of natural scenery by a Byron or a George Sand would differ from a scientific description of a mountain or a lake by Humboldt.

As to diagnosis, I cannot regard the symptoms mentioned, even in their totality, as pathognomonic of septicæmia, as all of them are to be found in other puerperal affections, when there is no evidence of septic absorption, unless with the author it be assumed that all puerperal disturbances are due to this cause alone. It is made an important point by the author to determine whether "the septic disease which is developing has originated in wounds situated between the os internum uteri and the vulva, or in the endometrium, above the former point." He says that "usually the question has to be decided by the efficacy or inefficacy of frequent germicide vaginal injections in bringing down the temperature and controlling other grave symptoms."

Now, I look at this subject from an entirely different point of view, and, as I have not the time to examine in detail the treatment inculcated in the paper we are now discussing, I must be content with the expression of my convictions by a few general propositions.

In puerperal fever, as met in private practice, we have to treat the *consequences* of some form of blood-poisoning. This may or may not be septic poisoning. In private practice, I think it generally due to some occult, possibly atmospheric, epidemic influence; in hospital patients, nosocomial malaria, often associated with septic poisoning.

No treatment which interrupts the normal physiological processes — such as the retrograde metamorphosis of involution, the fatty transformation of the component fibres of the uterus, or the cicatrization of its internal surface by the exudation of organizable lymph, and the development of a new layer of mucous membrane, or the healing of traumatic lesions—can be justified, unless positive symptoms, now well understood in science, demonstrate their necessity.

Antiseptic injections, both vaginal and intrauterine, are of great service when the indications for their use are clearly shown by local signs or general symptoms, but they cannot be recommended with safety as a routine practice on theoretical grounds, as, for obvious reasons, they may be most detrimental in retarding the cicatrization of lesions and the other processes of normal convalescence, and are otherwise sometimes dangerous. In several cases which I have seen with others, where antiseptic injections, both vaginal and intrauterine, had been used with all the care and precautions inculcated by the author and kept up for several days, the temperature rapidly fell, the profuse and sometimes offensive vaginal discharges speedily diminished, the pulse and general condition manifestly improved after the injections were discontinued.

I shall only add a few words in regard to refrigeration as a means of reducing fever in puerperal diseases. I have no question that it may be useful in some cases, but my own experience in this method of treatment has not been favorable. Many years ago I tried it in several cases in Bellevue Hospital, but I soon gave it up, as the results were less satisfactory than where other plans of treatment were pursued, and I know that this was the conviction of my house-staff. Cold will effectively and usefully reduce the temperature in active inflammations and acute fevers, but in adynamic diseases and in hectic fever this must be attended with a rapid waste of tissue more dangerous than the pyrexia. In three cases which I have seen with others—two a year ago and one this winter—where the coil had been assiduously kept over the abdomen, most of the time two or three days, the conditions in each were remarkably similar. The abdomen was blanched, colorless, and not sensitive to pressure; the patients all avowed that the coil gave them great comfort, but the temperature was very high in all—in one 104.3°, and in the other two over 105°; the pulse was very rapid and feeble, the heart's action extremely weak, with pulmonary symptoms—such as short, rapid, and shallow respiration—which caused grave apprehension that there might be latent centric pneumonia. After some discussion, I induced my friends to remove the refrigerating coil, and, in its place, to cover the abdomen with flannel saturated with the oil of turpentine, for the purpose of stimulating vaso-motor action, restoring the capil-

lary and equalizing the general circulation. All were taking quinine in large doses. This was greatly diminished or wholly stopped, and digitalis and ammonia in full dose were substituted. In a few hours the change in each of these cases was most remarkable; the temperature was reduced from two to three degrees, the pulse was greatly lessened in frequency and increased in force, and all pulmonary symptoms, which had caused so much anxiety, had disappeared. Two of these cases recovered and are still living. The third, who had also been treated by antiseptic vaginal and uterine injections, was apparently convalescent, when suddenly she became much worse; collapse supervened, which was found to be due to a sudden development of diphtheritic membranes, which covered the mucous surface of the vulva and vagina, the result of carelessness and dirtiness of the nurse. The patient died in a few hours.

I now ask permission to refer to a matter outside of the question of the prevention and treatment of puerperal fever, but in behalf of the "truth of history." I ask any who may feel sufficient interest, to turn to page 320 of my work on the *Puerperal Diseases*, where they will find on that and the following pages the subject of intrauterine injections fully discussed. Instruments for this use, which had been devised more than fifteen years ago, were shown to the class, and explicit directions were given as to the methods and indications for these injections, differing in no essentials from those we heard in this hall on the 6th of December. The lecture was delivered in the amphitheatre of Bellevue Hospital, in February, 1869, and the work in which it was printed was published in January, 1874. Then it may interest some to look at page 85 of Volume IV. of the *Transactions of the American Gynecological Society*, and read the papers by Dr. Edward W. Jenks, of Chicago, and Dr. James R. Chadwick, of Boston, on intrauterine injections, and the discussion which followed.

In conclusion, I shall only add that my creed today is fully avowed on page 476 of the book to which I have before referred, and, unless in the future I learn new facts and new arguments to change my faith, I shall "die impenitent."

A CASE OF MISTAKEN SEX.

By WM. P. McGUIRE, M.D.,
OF WINCHESTER, VIRGINIA.

A. B., thirty-five years of age and in good circumstances in life, consulted me on January 12, 1884, in order to have the sex to which she belonged determined. She was to all outside appearances a fairly formed woman about five feet four inches in height, with long hair curling down her back. Her voice and features were effeminate, and her demeanor was modest. From birth her dress had been that of a woman. All of her associations had been with women, and her business in life that usually followed by that sex. There was no hair upon her face.

I found upon examination that the conformation of her thorax was similar to that of a woman, and that her breasts were developed similarly to those of a young girl. The nipple was erectile. Her arms, hands, and lower limbs were like those of a man. There was a small penis in the natural position about three-quarters of an inch in length, with a well-formed glans and prepuce. It was capable of erection, but had in the glans no aperture. Following from the base of the penis backwards was a sulcus about one-half an inch in depth and two and a half inches in length. Lying upon each side of this sulcus, and each enclosed in separate scrotums, were two well-formed and developed testicles, each attached to a moderate sized spermatic cord, the whole conformation resembling the vulva of the female. There was no opening in this sulcus, but just at its posterior termination was an opening one-quarter of an inch in diameter, which was the external opening of the urethra, extending backwards and upwards into the bladder. No prostate gland was found. She stated that all of her proclivities and desires had been masculine, and admitted that occasionally in her sleep she had pleasurable sensations followed by an ejaculation of a white fluid from the opening of the urethra, which was, of course, an ejaculation of semen. There was no trouble in determining her sex. She was advised to change her dress to that of a man, and to attempt to have by a plastic operation a new urethra made from its termination in the perineum, along the sulcus to the glans penis, in order to effect more convenient urination, as she is now obliged to do so in the sitting posture.

ABSCESS OF THE TONSIL IN AN OCTOGENARIAN.

By SOLOMON SOLIS-COHEN, A.M., M.D.,
DEMONSTRATOR OF PATHOLOGY AND MICROSCOPY IN THE PHILADELPHIA POLYCLINIC.

Of one thousand consecutive cases of acute tonsillitis observed by Morell Mackenzie[1] at the London Hospital for Diseases of the Throat, but nine occurred in patients over fifty years of age, and in no instance was the patient older than sixty.

The following case is, therefore, worthy of record if only as a rarity; but by that very rarity it acquires a special diagnostic importance.

June 7, 1883, Mrs. V., aged eighty, was brought by her grandson to the office of Dr. J. Solis-Cohen, in whose absence the patient was examined by me. The lady was of sound faculties, and her bodily vigor was fairly well preserved. She had long suffered with dyspepsia and with chronic bronchitis, for which she occasionally consulted a practitioner of a "pathy," and four weeks previous to the time I saw her, this gentleman had been summoned to treat her for what he called "diphtheria." Two weeks later a quantity of blood and pus escaped from her mouth, and from that time the discharge had continued more or less copiously. There was occasional hacking cough, and degluti-

[1] Diseases of the Throat and Nose, vol. i. p. 49, London, 1880.

tion was painful., Her grandson became alarmed, and insisted that a physician should be consulted. He stated that he had looked into her throat, and had observed what he supposed to be a large tumor springing from her right tonsil. Inspection of the throat showed considerable tumefaction of the anterior palatine fold of the right side and enlargement of the corresponding tonsil, these structures being of a dark red, almost livid, hue. The middle portion of the tonsil was occupied by an irregular excavation of considerable depth, having ragged edges, and surmounted by a projection, irregularly spheroidal in shape, about the size of a filbert-kernel, and somewhat lighter in color than the surrounding tissues. The bed of the excavation was fungated, but there was no discharge nor covering of pus. From the history I concluded that the case had been one of acute tonsillitis, proceeding to suppuration; as a consequence of which the tonsil was left in the condition described. An application of the compound solution of iodine was made to the parts, and the patient was directed to return next day for the purpose of further examination by the gentleman whom it had been intended to consult. On this examination the diagnosis was confirmed, and the local treatment continued. In addition, there was ordered for internal administration, the solution of potassium arsenite, three minims to be taken in a teaspoonful of compound tincture of gentian, thrice daily, after meals. The patient was permitted to take her customary summering at the seashore, reporting for supervision at the end of a week, and again after a fortnight; one reason for thus keeping the case under observation being the diagnostic importance of positive exclusion of epithelioma,[1] which latter might justly have been suspected from the age of the patient, the appearance of the parts, and the unilateral manifestation. The sex of the patient did not favor this view; but the absence of cachexia and of glandular enlargements need not have militated against it, presuming the tonsil to be the seat of a primary epithelioma. It is true that this condition is rare, but tonsillitis in one so advanced in years is a still more unusual occurrence.

On July 16th the patient was finally discharged, the parts having remained for two weeks in a normal condition. During November, I was informed that this healthy condition had been continuous.

MEDICAL PROGRESS.

Phosphate of Codeia.—Dr. Fronmueller employs the phosphate of codeia for hypodermatic injection. He says (*Memorabilien*, July 16, 1883) that it possesses the advantage over the muriate and sulphate of being much more soluble. The substance crystallizes in slender, four-sided columns, is white in color and of a bitterish taste, and is soluble in four parts of water. Its action is very like that of morphia, but it is milder, and the symptoms of poisoning (such as great weakness, intense headache, bilious vomiting, etc.) are much less often encountered. It seldom causes local irritation when subcutaneously injected. The dose should be at least double that of morphia. The phosphate of codeia is especially recommended in the case of women and children.—*Practitioner*, January, 1884.

Vaginal Extirpation of the Uterus.—Breisky reports a case of total extirpation of the uterus by the vaginal method, on account of carcinoma, in a woman, æt. 60 years. The patient recovered, though it remains to be seen whether the malignant growth will recur.—*Centralbl. für Gynäk.*, January 5, 1884.

Parasite in the Onion.—M. Joannes Chatin has recently discovered a helminth in the common onion (*Allium cepa*), which has given rise to a disease. Pasteur has carefully studied the parasite, and found it similar to the parasite of mildew in wheat, but with less vitality. The best means for destroying it is to pull up the affected plants and burn them.—*Revue Scientifique*, January 5, 1884.

Reactions of Starchy Matters.—At the meeting of the Société de Biologie, on December 8, 1883, M. Dastre reported the results of his experiments on the reactions of starchy matters (starch, glycogen, and dextrine). The procedure which he proposes is founded on the fact that chloroform has the property of removing iodine from water. If we attempt to decolorize a solution of iodide of starch, we fail; we succeed, however, with pure glycogen; iodide of glycogen (an expression which Dastre employs for convenience of language) has a much weaker retaining power for iodine than has iodide of starch, and it is decolorized by chloroform.—*Gazette Hebdom.*, December 14, 1883.

Porro Operation.—H. Fehling reports his fourth Porro operation, which was successful both for mother and child. The patient was thirty-three years old, and the operation was performed on account of osteomalacia. —*Centralbl. f. Gynäk.*, January 12, 1884.

Treatment of Aneurisms of the Aorta.—In his inaugural dissertation, Dr. Lacointre gives the results of his observations on this subject, and draws the following conclusion:

Iodide of potassium is a sure means of calming the cough, dyspnœa, dysphagia, and the symptoms of compression due to aneurism of the aorta. It often produces a regression and atrophy of the aneurismal tumor, and seems also to give a greater prolongation of life than any other treatment. In a majority of cases it is well borne by the patients, and is quite innocuous.—*Revue de Thérap.*, January 15, 1884.

Hypodermatic Injections.—M. Luton divides hypodermatic injections into two great classes, according as it is necessary to make them in an alkaline or an acid medium. The alkaline medium—that existing in the subcutaneous cellular tissue—is the proper place for injecting neutral salts; the acid medium found in the muscular tissue is very favorable for the absorption of acid, alkaloidal, and certain metallic salts. The salts of mercury, for example, are absorbed with difficulty by the subcutaneous cellular tissue, and are liable to cause local inflammation; but when injected into the muscular

[1] This ossibility dictated the arsenic treatment.

tissue the absorption is complete, and local accidents rarely occur.—*Revue Scientifique*, January 3, 1884.

Nitrite of Amyl in Pneumonia.—Prof. Silvestrini, of Parma, formulates his conclusions as to the value of nitrite of amyl in pneumonia as follows:

1. In the preorganic stage of pneumonia, the nitrite of amyl may be of prompt and effective service.

2. One may repeat with impunity the inhalation of this remedy during several successive days, and in doses relatively enormous. (He has administered as much as fifty grammes of the nitrite in five days, the inhalation being carried on for five minutes every half hour.)

3. In cases which have a fatal issue, whether from extension of the pneumonia, or from complications, these inhalations may retard death.

In the brief note of his experience with the nitrite four cases are recorded. In the case of a man, fifty-nine years of age, suffering from double pneumonia, which had reached its fifteenth day, the nitrite was commenced under the following conditions: Pulse very small, 120; respirations superficial, 44; temperature, 101.5°; stupor, cyanosis of the face and extremities, coldness of the point of the nose, and tracheal râle indicating the approach of a fatal termination. At the end of five minutes, during which twenty drops of the nitrite of amyl were administered, the stupor appeared less, but the other phenomena persisted. The inhalations were repeated during the night, about ten grammes being thus given. In the morning pulse 120, respiration 64, temperature 101.3°, with less cyanosis, and signs of commencing resolution. With progressive improvement two days later the pulse was 96, respiration 36, and temperature 100°, and in a few days the patient was convalescent.—*Glasgow Med. Journ.*, January, 1884.

Ulcerous Typhoid Sore Throat.—Dr. E. Rapin, in a communication on this subject to the Société Médicale of Geneva, draws the following conclusions:

1. Typhoid fever affects the throat more often than is generally supposed; in fact, the first symptom may be a sore throat of an ulcerous nature.

2. The ulcerations are superficial, rounded, or, more usually, oval, with a slightly elevated border, hard floor, ordinarily indolent, and generally situated on the anterior pillars of the fauces, and on their anterior face.

3. Their diagnosis is sometimes very difficult; it is only by frequent examination and attention to the general symptoms that they can be certainly recognized. These ulcers seem specially to affect the lymphatic system; the lesions of the lymphatic apparatus are identical with those found elsewhere in the course of typhoid fever.

4. Their development is due to the direct penetration of the typhoid germs into the follicles of the faucial region.—*Revue de Thérap.*, January 15, 1884.

Arsenic as an Antipyretic and Parasiticide in Relapsing Fever.—Bogolomow reports four cases of relapsing fever treated with Fowler's solution. The first was that of a man, æt. 36. Treatment was commenced on February 14, 1883. The morning temperature was 103° Fah., evening temperature 105°. The spleen and liver were enlarged; there were petechiæ under the skin, and numerous spirochætæ were found. On Feb. 15, the morning temperature was 103°, evening temperature 104°. Gtt. iv of Fowler's solution were injected under the skin; five hours afterwards, the temperature sank to 92.5°, and the pulse from 100 to 60. On the following day, the temperature was still 92.5°, and no micro-organisms could be found.

On the twelfth day after the beginning of the attack, the temperature rose suddenly to 104.8°, and large numbers of the micro-organisms were found in the blood. The solution was again injected, and with the same result as before. The effect on two of the other three patients was equally good. The temperature and pulse rates were promptly reduced, and the micro-organisms disappeared from the blood.—*Centralbl. für klin. Med.*, December 29, 1883.

Modifications in Muscular Structure after Nerve-section.—M. Babinsky has recently presented a communication on this subject to the Académie des Sciences. These modifications consist essentially of simple atrophy of the contractile substance with multiplication of the sarcolemma cells. Babinsky shows that atrophy of the contractile substance progresses in direct proportion to the development of the protoplasmic structure; this dissociates the primitive cylinders, and thus brings out the field of Cohnheim much more distinctly than in the normal state; it accumulates in certain fasciæ, at their periphery and between the sarcolemma and the striated substance, in other fasciæ at their central part, so that the striated substance is turned back toward the sarcolemma. This last disposition is particularly interesting, because the altered muscular fibres are exactly similar to muscular fibres in process of development.—*Revue Scientifique*, January 12, 1884.

Antagonism of Pilocarpine and Ergotine.—M. Rabuteau reported at a late meeting of the Société de Biologie that there is an antagonism between pilocarpine and ergotine, the first substance acting as a vasodilator poison, the second as an excitant of the unstriped muscular fibres.—*Gazette Hebdom.*, December 14, 1883.

Pilocarpine in Scarlet Fever.—Mr. Frank Shearar reports a severe case of scarlet fever, with convulsions, treated successfully by subcutaneous injection of pilocarpine, gr. $\frac{1}{15}$. Soon the skin became moist, and in from ten to fifteen minutes the patient was salivating, and was bathed in a profuse perspiration, great beads of sweat standing on the face, and, in the course of fifteen minutes after the injection, and an hour and twenty-five minutes from their first appearance, the fits ceased and never recurred. Therapeutically considered, it is very interesting to find that when venesection to a very fair amount had failed, the pilocarpine first showed its marked physiological effects, and then stopped the fits, and that after such a lapse of time as quite to put it beyond all reasonable doubt that the venesection had very little to do with the successful result. Indirectly, perhaps, it aided it, as did also the application of the hot pack, which was kept up very industriously; yet both of these methods of treatment were in operation for upwards of one hour and a half without in the least modifying the fits.—*Glasgow Med. Journ.*, January, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 16, 1884.

THE DISCUSSION UPON PUERPERAL SEPTICÆMIA.

OUR present number has the conclusion of the discussion at the New York Academy of Medicine of Dr. Thomas's paper upon "The Prevention and Treatment of Puerperal Septicæmia."

Dr. Thomas, believing in a specific poison as the cause of so-called puerperal fever, proposed ten rules which he stated ought to be carried out in every case of confinement, for the purpose of preventing the disease. Some of them are wise and practicable, but others seem to us utterly useless. For example, what is the necessity of giving every four hours antiseptic vaginal injections to a woman in labor when there is as yet no traumatic surface—vulval, vaginal, cervico-uterine, or intra-uterine; and when there is ordinarily such abundant secretion from the birth-canal that absorption is in the highest degree improbable, if not impossible? Again, the suppository of iodoform (three to five grains, with cocoa butter) which, after labor, is to be passed up under the os uteri every two or three hours, may open the vulvo-vaginal door for the entrance of more disease-germs from the atmosphere than the iodoform can kill. Every eight hours the patient has a warm antiseptic vaginal injection. Finally, an antiseptic catheter is to be antiseptically used, if the instrument be necessary—and the necessity will be apt to come to a patient who has such luxury of attentions as are directed. Whence it will be seen that the patient's genital organs are more or less disturbed fourteen to eighteen times in the twenty-four hours. We must believe that physical and mental rest has as much to do in helping puerperal convalescence as microbes have in causing puerperal disease.

In reading Dr. Thomas's elaborate directions, the passage in *Rasselas* comes to mind, "Thou hast convinced me it is impossible to be a poet;" and, similarly, each woman to whom these ten commandments are read and expounded, would be apt to think, if not to say, "Thou hast convinced me it is impossible to have a baby and live." We do not believe one physician in a hundred will endeavor to secure the observance of all these rules; the prophylaxis of puerperal septicæmia—and this prophylaxis is of great importance—ought to be simpler, less complicated, less perturbing and disturbing Nature's processes. Intensely earnest, thoroughly honest, and gifted with rare oratorical power, as Dr. Thomas is, we do not wonder that so many of the Fellows of the Academy heartily indorsed his utterances, but only that any one dared to controvert them.

Dr. Thomas, in his brief reference to the outbreak of puerperal septicæmia, speaks of the disease beginning with a chill. Now, this statement may mislead some who have never seen the disease, and therefore we beg leave to remind them that in some cases a fatal lymphangitis, metritis, or peritonitis, or a general septic poisoning, without distinct localization, at least discovered during life, may occur, and Nature give no cry of alarm by a chill preceding the symptomatic fever.

In the treatment of the affection, Dr. Thomas advises hypodermatic morphia, antiseptic intra-uterine injection, reduction of temperature by the use of ice-water in Townsend's coil and by quinine, or by Warburg's tincture (a preparation which will generally be found disagreeable to patients, and which, considering the multiplicity of its ingredients, is hardly worthy of scientific recognition), and support by milk and animal broth. Probably the antiseptic intra-uterine injections are the most important part of this treatment. Dr. Thomas has not said a word too much in their favor, but it is to be remembered that Dr. Barker has also warmly advocated them, as may be seen by consulting his very valuable work on *Puerperal Diseases*, and the fourth volume of the *Transactions of the American Gynecological Society*.

The discussion was opened by Dr. Barker, who endeavored to overthrow the septicæmic theory, presented by Dr. Thomas, as well as criticised somewhat the treatment he advocated. Dr. Barker is well known as possibly the ablest of all advocates of the essential nature of puerperal fever; he presents the argument strongly, but chiefly as the result of his own observation, not bringing to bear, or at least only slightly, the large historical resources he has at such ready command, nor fortifying any of his positions by the authority of great teachers: yet

one might find in the writings of the veteran obstetrician of Strassburg, Stoltz, some facts and opinions that are not easily, or at all, reconcilable with some of the positions of Dr. Thomas; similar facts and opinions may also be found in a recent paper by Eustache in the *Archives de Tocologie*. We almost wish these had been presented, so that we might have the answer of Dr. Barker's chief antagonist.

After Dr. Barker's paper had been read, and he had supplemented it by some extemporaneous remarks, several Fellows participitated in the discussion, which was afterward closed by Dr. Thomas. In this closing speech the brilliant orator seems to us to have been somewhat discursive; the speech appears even weak in its beginning, but strong and clear in its progress, some passages, indeed, rising to the noblest eloquence, and powerful in its conclusion. A few hard blows were given, but they were given with knightly courtesy and without malice. In the course of this speech the brilliant orator, taking the statement that had been made by Dr. Hanks, to the effect that upward of two hundred and fifty women died every year in New York from puerperal septicæmia, concluded that ten thousand died from this cause every year in the United States, a conclusion which is in a high degree improbable, for the disease is much more frequently seen in large cities, and especially in lying-in hospitals, than in the country.

In the essential positions taken by Dr. Thomas in this speech, he is sustained by leading obstetric authorities; this remark especially applies to his assertion that puerperal septicæmia is dependent upon micro-organisms. Incidentally, we may observe that we wish Dr. Thomas, or some one holding his faith, had quoted in the discussion some of the evidence in favor of antiseptic obstetrics which Dr. Paul Bois has collected in his *Methodes Antiseptiques en Obstetriques*, Paris, 1883. Admitting that a specific poison is the cause of puerperal septicæmia, such obstetrics has a scientific formation; while, on the other hand, the most remarkable results from the use of antiseptics in obstetric practice come to confirm the theory—*cura ostendit morbum*.

This discussion was most able in character, and it will have a wide-reaching and lasting influence. Whether or not all believe with Pajot that the term puerperal fever ought to be consigned to the museum of antiquities, certainly all will be quickened to see that labor and the puerperal state shall be rendered as far as possible aseptic. While we do not accept, as before indicated, all of Dr. Thomas's rules, others are of great importance, and on occasion should be urged upon the profession. And we wish he had supplemented them by an earnest protest against the interference with physiological labor by digital or manual dilatation—the meddlesome midwifery, which is practised by some, we hope a very small minority of, doctors. It would be much safer for the patients, and their liability to septicæmia would be less, if these practitioners were to keep their hands in their own pockets during the whole course of labor, instead of using them as dilators of the uterine or vaginal orifice.

Proposing at an early day to consider the subject of puerperal septicæmia, we now take leave of the New York discussion.

OGSTON'S OPERATION FOR FLAT-FOOT.

AT the meeting of the Medical Society of London, January 14th, PROF. OGSTON, of Aberdeen, read a paper on the mechanism of pes planus, and its treatment by a new operation, which may be found in the *Lancet* for January 26th. The key to the disease is constituted by the relaxation of the ligaments, and the changes in the scaphoid bone and head of the astragalus, which form the inner half of the medio-tarsal or Chopart's articulation. On the under surface of the joint the bones are separated from one another, while the pressure between them is increased on the upper side. Hence, the mutual relations of the articular facets are changed; growth is checked, or absorption takes place, at the upper halves; and there is increased growth of the separated surfaces of the lower halves, which takes place mainly in the astragalus, its head being somewhat square in form and presenting an abnormal ridge or projecting angle, which divides its anterior facet into two portions, of which one articulates with the scaphoid, and the other with the inferior calcaneo-scaphoid ligament. The ridge or angle, in the permanent stage of the deformity, finally projects so much that it locks on the scaphoid, and renders reduction impossible until it is removed. In such cases the head of the astragalus escapes partially from the scaphoid downwards and inwards, so as to form on the inner side of the sole a much larger prominence than that of the scaphoid.

The object of the operation devised by Mr. Ogston is to restore the astragalo-scaphoid joint to its normal position and rigidity, at the expense of producing anchylosis, by denuding the bones of their cartilaginous surfaces, placing the foot in a proper position, and securing its immobility by uniting the two bones with ivory pegs. Bearing in mind that the projecting head of the astragalus lies on the inner side of the sole, about an inch in front of the malleolus, and that the scaphoid is comparatively indistinct, the operation is done, under strict antiseptic precautions, in the following manner:

The foot, grasped by the hand of an assistant, having been placed with its outer side resting on

the table, an incision, commencing an inch from the tibia and carried for an inch and a quarter down to the bones, along the inner side of the sole over the joint, exposes the centre of the latter. The articulation having been freely opened by separating the attachments of the ligamentous capsule to the edge of the scaphoid for half an inch on each side of the wound, the cartilage and thin bony lamina of both the astragalus and scaphoid are removed with a sharp chisel, half an inch broad, through which the cancellous structure of the bones is laid bare. The arch of the foot having then been restored to its normal shape by the assistant depressing the metatarsus, two holes are drilled through the scaphoid into the astragalus, and small ivory pegs driven home, their projecting ends being cut off on a level with the scaphoid by a bone forceps. The lips of the wound are next united with catgut sutures, Lister's dressings applied, and the foot steadied with a few turns of plaster-of-Paris bandage. The patient is kept in bed for two or three months, and is able to walk freely in a week or two afterwards.

Mr. Ogston has performed the operation, thus briefly described, seventeen times on ten patients. In not a single case did the temperature rise above 100° F. The wounds remained aseptic, and the dressings were renewed only a few times. In all great benefit resulted, and in the majority a bony anchylosis and a painless arch were obtained, permitting the subjects to resume their laborious occupations. In one case an ivory peg was spontaneously extruded at the end of five months, but in the remainder it gave rise to no inconvenience. In a few the plantar arch was perfectly restored, while in all it was much improved, and added to the lightness of the patient's step.

With such results before us, we have to congratulate Mr. Ogston upon having brought forward this excellent operation for so troublesome and painful an affection as flat-foot in its confirmed stage. Under strict antiseptic precautions, it will doubtless yield good results in the hands of other surgeons, and we hope to see it fairly tested on this side of the Atlantic.

THE RELATIONS OF TUBERCULAR PHTHISIS TO DISEASES OF THE EAR.

THE coexistence of ear affections, accompanied by purulent discharge, and of tubercular phthisis, has been noted. At times, a discharge from the ear will have been first observed, followed speedily by tuberculosis of the lung; or the tuberculosis is first recognized, and there speedily follows a discharge from the ear, not in the last stages of the consumption, but while the patient is still strong, or, it may be, apparently improving as to the lung affection. In these cases there is usually observed a minute perforation of the drum of the ear at its lowest portion, which on this account is not easily recognizable. The patient, however, calls the physician's attention to it, because, in the act of sneezing, he hears the hissing sound produced by the air rushing through the opening in the membrane.

PROF. VOLTOLINI has sought to determine the relation of these two conditions, and published a preliminary communication in the *Deutsche med. Wochenschrift*, Jan. 10th. The question, of course, is, have we here a simple catarrh of the ear, an accidental concomitant with tubercular disease, or are they both the result of the same cause—in a word, tubercular? Prof. Voltolini has come to the latter conclusion, and bases his view upon the fact that he has found with absolute certainty Koch's bacillus in the discharge from the ear in two such cases.

OSTEOPLASTIC RESECTION OF THE ANKLE-JOINT.

THE most recent improvement in excision of the ankle-joint, and it is one which appears to have had no followers in this country, is the operation devised by Professor MIKULICZ, of Vienna, and described by him in *Langenbeck's Archiv*, Bd. xxvi. It is particularly adapted to cases in which caries is limited to the ankle-joint and the calcaneum, and affords a far more useful stump than does amputation through the lower part of the leg, or Pirogoff's operation, or Syme's amputation.

As we do not happen to have before us the original article, we copy from the last edition of *Gross's System of Surgery* the mode of performing the operation: "An incision is carried across the sole of the foot down to the bones from just in front of the tuberosity of the scaphoid to a point just behind the tuberosity of the fifth metatarsal bone. From the extremities of this cut, a second incision is extended on each side upwards and backwards to the corresponding malleolus, and united by a transverse incision through the posterior circumference of the leg down to the bones. The foot being flexed, the joint is opened from behind; the astragalus and calcaneum are carefully separated from the soft parts; and the knife is carried through the medio-tarsal articulation. The malleoli and the articular surface of the tibia, along with those of the cuboid and scaphoid bones, are then removed, and brought in apposition." During the subsequent treatment, the foot is kept extended, so that, after the parts are thoroughly united, the patient may walk on the heads of the metatarsal bones, as in talipes equinus.

The results of the operation are recorded by LAUENSTEIN and MIKULICZ in the *Centralblatt für Chirurgie*, No. 1, 1884, and the *Przeglad Lekarski*,

Nos. 36 and 37, 1883. Of Mikulicz's 3 cases, all recovered with good progression, but one died of pulmonary tuberculosis in nine months. Of Lauenstein's 2 cases, 1 recovered with good progression, and 1 died in eight months, of phthisis, which existed at the time of the operation, and was, therefore, an improper one for the procedure. In a sixth case, in the hands of Socin, the patient walked well. In all of the recoveries, the limb was lengthened, as a rule, from three-fifths to four-fifths of an inch, and one and two-fifths of an inch in the case of Socin, but the difference in the length of the limbs was equalized by a high-soled shoe worn on the sound foot.

THE RADICAL CURE OF CONGENITAL HERNIA.

IN last week's issue of THE MEDICAL NEWS, we directed attention to the modern operation for the radical cure of hernia. In this connection, it may be interesting to note that in congenital inguinal hernia the modern procedure is attended with peculiar difficulties; not only are the isolation and complete extirpation of the sac rendered almost impossible from the firm adhesions which exist between it and the cord and the testis, but the structures of the cord are spread out like a fan, the sac lying, as it were, in its centre. In these cases the surgeon must content himself with partial excision of the sac, and the question may arise whether, on account of the elongation and isolation of its vessels, whereby the vitality of the testis is endangered, it may not become necessary to sacrifice that organ.

KRASKE, in a paper contributed to the *Centralblatt für Chirurgie*, No. 1, 1883, recommends immediate castration; but this practice is warmly and justly opposed by Sonnenburg and Zeller, in the *Berliner klinische Wochenschrift*, Nos. 48 and 51, 1883, as being unnecessary and calculated to throw discredit upon the procedure. Instead of excising portions of the sac, Hahn has successfully resorted, in six cases, to obliteration of the serous surfaces by a row of catgut sutures.

The statistical results of the modern operation indicate that of eight cases in the hands of Zeller, Maas, Von Wahl, Busch, and Czerny, two were fatal—a mortality which demonstrates that it should not be resorted to unless for weighty reasons.

AN INSTITUTION FOR BIOLOGICAL RESEARCH.

IN his Presidential Address before the New York State Medical Society, DR. HUTCHINS calls attention anew to the almost utter neglect in this country of organized facilities for systematic instruction in biology. Harvard and Johns Hopkins are about the only schools offering any real opportunities. In this city, facilities of the kind are entirely wanting. None of our medical schools offer any such instruction. At the Academy of Natural Sciences, the rich museum, and the fine library and lectures on geology and mineralogy, are the only means afforded. They are splendid in themselves, but utterly inadequate to satisfy the wants alluded to. Accordingly, Dr. Harrison Allen has suggested in *The American* for January 26th, that a new institution—"The Biological Institute of Philadelphia"—should be established, with a director and an assistant as teachers. The expenses, he proposes, should be met partly by the fees paid by the students and partly from an endowment, which he suggests would be a fitting memorial of our great scientific gathering next September.

We certainly second the suggestion, and as heartily as possible. It is a most urgent need in this great city. We know of many students, men and women, who have been driven to Europe or to Baltimore by just such a lack of opportunity to study at home, to say nothing of the large number who would be drawn hither by such an institution. Its natural affiliation would be with the Academy of Natural Sciences, for, in its library and its museum nearly every possible want in these directions would be filled. Moreover, we have among us just the man for the place of director, a man of the widest reputation, of untiring energy, a tried and trusted teacher—no one could be named who could compete with JOSEPH LEIDY for the place.

GENERAL GRANT'S HEALTH.

THE condition of General Grant's health has, of late, been the subject of numerous newspaper paragraphs, containing gloomy prognostications. It, therefore, affords us pleasure to be able to state authoritatively that General Grant is doing very well, although his recovery from the effects of his fall has been delayed by an intercurrent rheumatism, affecting first the uninjured limb and then flying about to various regions. He walks about the house on crutches, and is waiting only for pleasant weather to go out.

PROFESSIONAL OPINION OF THE NEW CODE.

IN the discussion on the New Code at the late meeting of the New York State Medical Society, Dr. Roosa is reported to have said that "Letters had been received from the best men of many States, urging New York State to stand firm in shaking off the shackles of the so-called National Association, and promising that other Societies would follow the example."

It is greatly to be regretted that Dr. Roosa did not read these letters, so that the profession could have had an opportunity to form its own estimate of

the men who wrote them. However, we hope they will yet see the light of day, and not share the sad fate of those "heartiest endorsements of the course of the *Record* in its advocacy of freedom in consultations," which our New Code contemporary proudly said it too had received "from influential men in every part of the country," but which, notwithstanding our frequent and reiterated requests, it never showed its willingness to produce.

On looking over the yeas and nays on the vote to restore the National Code, we find that of the prominent New York members present, the following voted in favor of the New Code and against the National Code: Drs. C. R. Agnew, T. A. Emmet, A. Jacobi, A. L. Loomis, D. B. St. John Roosa, and F. P. Foster, of the *New York Medical Journal*, and G. F. Shrady, of the *Medical Record*.

REVIEWS.

DE L'ANUS CONTRE NATURE ILÉO-VAGINAL ET DES FISTULES INTESTINO-UTERINES. Par le DR. L. H. PETIT, Sous-Bibliothécaire a la Faculté de Médecine de Paris. 8vo. pp. 223. Paris: H. Lauwereyns, 1883.

ILEO-VAGINAL ARTIFICIAL ANUS AND INTESTINO-UTERINE FISTULÆ. By DR. L. H. PETIT.

WORKS on gynecology and the chapters on the diseases of women in works on surgery make but little mention of these affections. A case of ileo-vaginal anus, seen at the Hospital de la Pitié, in the service of Professor Verneuil, has recently caused M. PETIT to look up the literature of the subject. He has only found a few pages descriptive of the affection in classical works, but has found a large number of cases reported.

These cases, numbering twenty-three, have enabled him to describe accurately the causes, pathological anatomy, the symptoms, diagnosis, and treatment of ileo-vaginal anus. The affection follows strangulation of the intestine in a ruptured vagina, as a result either of an inflammatory or cancerous affection, which causes an opening of the intestine and vagina, and communication between the two.

As the process is the same, whether taking place in the uterus or vagina on the one side, and the intestine on the other, M. Petit has described ileo-vaginal anus and utero-intestinal fistula at the same time; the two affections only differ from the point of view of prognosis and treatment, but the points common to both are very important in practice from a diagnostic point of view, and it is on this account that M. Petit has described them together. With twenty-three reported cases of ileo-vaginal anus and sixteen cases of utero-intestinal fistulæ, he has compiled a monograph to which the Académie de Médecine awarded, in 1881, the Huguier prize—three thousand francs—and which has been recently published in the *Annales de Gynécologie;* and a brief *résumé* of it appeared in THE MEDICAL NEWS for Nov. 17, 1883.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 7, 1884.

THE PRESIDENT, FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

THE evening was devoted to an adjourned discussion of the paper by DR. T. GAILLARD THOMAS on

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER,

which was read on the 6th of December.

THE PRESIDENT, DR. FORDYCE BARKER, opened the discussion by the reading of a paper on this subject (see page 182).

He prefaced it with the following remarks:

During the five years which I have had the honor to occupy this Chair I have never before seen a meeting of this Academy so enthralled by the charm of elocution, the fascination of rhetoric, the glow of conviction, and the air of one who speaks by authority—an air which can never carry weight unless it has been before fairly and justly earned by good work—as on the evening of December 6th, when the paper was read on "The Prevention and Treatment of Puerperal Fever."

Its authoritative tone, its earnestness and sincerity, its coloring of being based on experience and observation, instead of being unconsciously deduced from preconceived theory, give the paper such a plausible air of scientific truth as must secure its acceptance without question by many minds whose belief rests on authority, without examination of the data or analysis of argument. The more eminent the author of errors which may dangerously influence medical practice in matters of such vital importance as the saving of life of those who have just become mothers, the more striking the literary excellence and the more admirable the artistic merits of a paper promulgating such errors, the more necessary it is that such errors should be boldly met and promptly refuted. Any paper read before this Academy, by one to whom all concede a place among the most eminent in the department of the profession to which his life has been devoted, if allowed to pass without examination and discussion, will be accepted by great numbers in all parts of the country as a statement of the science and medical practice as enunciated by the most prominent men of the period. It is therefore a duty to examine carefully those novelties in doctrine and in practice which are brought here, and subject them to the test of the advanced science of the day and the accumulated experience of the past.

All will agree that the paper was remarkable for its originality, in that some of its pathological doctrines and the practice inculcated for the prevention and treatment of puerperal fever have never been taught in any work on obstetrics, or by any writer of acknowledged repute. If they are accepted by the common intelligence of the profession, they will assuredly be found in the obstetrical works of the future.

As there are many others who will take part in this discussion, whom all will be anxious to hear, and as the author of the paper is entitled to all the time he

may wish to close the debate, I shall, in the most concise language consistent with clearness of statement, give my reasons for thinking that the whole tone and coloring of the paper are misleading and dangerous, because it is supersaturated with septic infection. I would not "speak disrespectfully" of puerperal septicæmia. I believe it to be one of the most dangerous incidents which may occur to women after childbirth, and I trust it will not be regarded as indelicate if I allude to the fact that in a work on puerperal diseases, published more than ten years ago, a lecture devoted to the consideration of this subject in all its relations fills thirty-seven pages. With the most anxious desire to correct any errors of opinion, and to accept any new views which progressive science or increased and more accurate clinical observation have demonstrated to be true, I have yet found no reason to make any essential change of the views expressed in that lecture.

At the conclusion of the paper Dr. Barker made a few extemporaneous remarks, in which he said that in the early part of his professional career he had used antiseptic vaginal injections. Nearly thirty years ago at Bellevue Hospital he had employed Labarraque's solution for this purpose, keeping up the injections for almost a week after labor. Subsequently carbolic acid was substituted for this, and in his work already referred to he had given the formula which he had always made use of. This practice he had habitually maintained, both in private and public practice, until within the last three years. While attending the meeting of the International Medical Congress in London, in 1881, he was sitting on one occasion next to Thomas Keith, of Edinburgh, and was very much impressed by some remarks which he made on the subject of antiseptics in ovariotomy. They were so suggestive that they caused him to give the matter in its relations to the parturient woman very deep reflection, and he began to ask himself whether many of the interruptions to convalescence which he sometimes met with in his obstetrical practice were not really due to the carbolic acid injections employed. On his return to New York in September, therefore, he reduced one-half the strength of the solution of the acid which he was accustomed to use, and so pleased with the results thus obtained was he, that after a time he gave up using vaginal injections altogether. He felt the less reluctance in doing this from the reflection that even in its strongest form the strength of the solution was not sufficiently great to destroy microorganisms, if any were present. He also asked himself whether nature did not act wisely in bathing all the parts concerned in the process of parturition with that bland but malignant fluid—the lochial discharge—and, consequently, whether it were not better to leave all the parts at rest, in imitation of the surgeon in the treatment of wounds.

It was now fully two years since his colleague, Dr. A. A. Smith, and himself had ceased using vaginal injections altogether, as a rule. It was now his practice, therefore, in every instance to direct the nurse not to use injections unless expressly ordered to do so, in consequence of some special condition calling for it. The results had been exceedingly satisfactory, and since September, 1882, when the injections were given up, neither he nor Dr. Smith had had a single case in which there had been any interruption to recovery, or in which it had been necessary to give more than the ordinary attendance, viz., one daily visit for nine days after labor. This might be simply a coincidence; but his experience had been so suggestive that he trusted that others also would try the experiment and make known the results met with.

DR. W. M. CHAMBERLAIN said that he would merely like to make one or two remarks in regard to his tube, to which Dr. Thomas had referred in his paper, and which he stated he had had occasion to modify by making an opening just at the extremity, and by bringing the other openings nearer the latter. One of these modifications (the second) he had already anticipated himself, and he could see no objection to the other. One of the gentlemen who took part in the discussion of Dr. Thomas's paper said that he had found the tube too large; but in all the autopsies of patients who had died from puerperal septicæmia which he had seen, the uterus was found to be large and flaccid; while if the uterus was firm and globose, he was accustomed to look for some other cause of death than septicæmia. It was only in this large and flaccid uterus that the tube was required at all, and hence he believed that it was desirable that the tube should be large. Another reason why he had made the tube as large as three-eighths of an inch in diameter was that it was designed to act as a lever as well, and by lifting up the anterior lip of the os uteri, allow ample room for the escape of all the fluid used in the injections. As to the objection that on account of the vaginal openings all the fluid was liable to escape from the tube before it reached the uterine cavity, he did not think it was valid, because by reason of the smallness of these orifices as compared with the large capacity of the tube, it was impossible that all the fluid should thus escape. In regard to the general subject before the Academy, he hoped that Dr. Garrigues would be heard from, since his recent observations were of great interest, and seemed to be of practical importance.

DR. H. T. HANKS believed that Dr. Thomas's paper would have a vital and lasting influence upon the practice of obstetrics in this country, and that when the rules which he had laid down for the prophylaxis of puerperal fever were generally adopted by the profession, the mortality of childbirth would be materially diminished. This was a disease which was not confined to the cities. During the five years in which he had engaged in rural practice in Massachusetts, he had one case, and this he proceeded to relate. He also mentioned other cases occurring in the country, and then went on to say that he believed that at the present time the profession was ready for any judicious plan which promised better results than those attained in the past. The vital statistics of New York showed that in the year 1883, out of 31,669 women who had been confined, 262 had died; which in the four years, 1880, 1881, 1882, and 1883, the mortality had been 1005. These were startling figures, and it was a reflection worthy of consideration, that many of the victims of puerperal septicæmia would not have contracted it if proper measures had been adopted for its prevention, or, if they had been attacked, might have been cured by appropriate treatment. That the profession in this city was becoming alive to the importance of septicæmia as a concomitant of parturition, however, was shown by the fact, that each year the relative number of cases reported as puerperal septicæmia, as com-

pared with those given under the old designation of puerperal fever, was increasing. During the past fifteen years he had attended about sixty-five cases of midwifery a year. Among these, some of the patients had had puerperal fever, and there had not been a single case of this in which all the trouble could not be satisfactorily explained on the hypothesis of septicæmia.

As a whole, he thought that Dr. Thomas's rules for prophylaxis were admirable, though there were one or two to which he would take exception. The ante-partum injection he thought was unnecessary; the use of the napkin over the vulva being sufficient before labor. The administration of ergot three times a day for a week he believed to be neither necessary nor justifiable, as the drug was harmful except in certain cases where the uterus did not contract well. If laceration of the perineum were found to have occurred, he advised that one deep suture (two at most) should be taken and secured with shot. In no case should the long loops of silver wire be left to become a source of irritation. If the patient, however, were greatly exhausted, or if the laceration extended through the sphincter ani, the primary operation was to be postponed, since even the secondary operation sometimes gave rise to severe fever, and subjected the patient to more or less danger. He fully agreed with Dr. Thomas as to the utility of frequent vaginal injections; but he was not favorably impressed by the use of the iodoform suppository.

In regard to the treatment, he had only one or two suggestions to make. One was that the administration of aromatic spirits of ammonia, in doses of half a teaspoonful, every two hours, would be found of service. In making use of the intrauterine injections, he thought with Dr. Hunter that it was not advisable to move the patient to the edge of the bed, as Dr. Thomas had recommended; and in order to avoid this, he had devised a simple bed-pan of block-tin, constructed in such a way that the patient could lie upon it with perfect comfort, and that the injections could be made with great facility. (This bed-pan was now exhibited by Dr. Hanks.) It was only proper to use intrauterine injections, he believed, when there was a strong probability that the cause of the trouble was within the uterus. The refrigerating coil he thought of service in certain cases. A few of Dr. Thomas's suggestions, however, could be safely dispensed with. In conclusion, he said that there were four assistants upon which he always relied in his management of obstetrical cases, and these were—pure air, absolute quiet, judicious diet, and the use of appropriate antiseptic measures.

Dr. William T. Lusk remarked that the papers of Dr. Thomas and Dr. Barker, although apparently so antagonistic, in reality seemed to supplement each other in many points, and, therefore, we could hardly spare either of them. To him, personally, puerperal fever was precisely the same as surgical fever. He believed in their absolute identity. There were great difficulties in the way of constructing a good definition of puerperal fever, and no two authors seem to be able to agree in defining it. Puerperal women were peculiarly susceptible to extraneous poisons, and hence when such women contracted diseases, like scarlet fever, for instance, the affection should be regarded as a complication. As regards the relations between puerperal and surgical septicæmia, there were certain dissimilarities in the two which were due merely to anatomical differences. In the latter there was a clean-cut wound, while in the former we had an œdematous condition of the cervix, enlarged veins, and lymphatics, and other mechanical conditions, which peculiarly favored absorption. Hence, if the same septic matter were brought in contact with a clean-cut wound, and with the genital organs of a woman after parturition, certain differences in the effects produced would be noticed. There was not only the rapidity of absorption, but the nearness of the peritoneum to the uterus, to be taken into consideration in the case of the parturient woman. A great deal of confusion and difference of opinion had grown out of the fact that writers did not keep in mind the marked distinction between putrid intoxication and septicæmia. The distinction between the two, which was thus too often lost sight of, depended simply on the presence or absence of certain micro-organisms in a decomposing fluid. Rod bacteria, it had been demonstrated, were not absorbed in the human subject, and if carried on the hands of the accoucheur to the maternal parts, there was no danger of their communicating sepsis. The putridity of any discharge, therefore, was not the source of septicæmia proper. Putridity, however, was to be regarded as a warning that the round bacteria, which were the real source of danger, were likely to be generated. These were capable of being absorbed, multiplying rapidly, and becoming distributed to the various parts of the organism. They often penetrated to a distance from the lesion by which they entered the system; but if they were of feeble activity they might merely give rise to local inflammations, like cellulitis or peritonitis. But it was not the pathology which he wished to discuss on this occasion; though on account of the fact that the two forms mentioned were so frequently confounded, he had thought it well to allude to them, especially as the treatment most successful in the one was not adapted to the other.

In regard to the prophylaxis, Dr. Lusk said that he thought that we should be careful not to lay too much of a burden upon the practitioner in the way of minute details, which might not, after all, be of much consequence. For instance, he should not expect much benefit from washing the walls and furniture with antiseptic fluid. This opinion was founded upon his experience in hospitals. In the lying-in wards of Bellevue Hospital there had been no pictures on the walls, and no superfluity of furniture, and it had been the practice to wash thoroughly the walls, floors, and such furniture as there was with a five per cent. solution of carbolic acid; but this procedure had never had the slightest effect in preventing the development and spread of puerperal septicæmia. He had his doubts, therefore, whether the observance of this rule would be of benefit in private practice. Afterwards, he had been in the habit of fumigating the hospital wards with sulphurous acid, as was the ordinary practice of the sanitary authorities in houses where cases of infectious disease had been found. In private practice it was certainly the part of prudence to adopt this precaution before attending a case of confinement in any house where there had been a case of diphtheria, scarlet fever, or other similar affection, if it had not already been done. One point which was of considerable practical importance, he thought, was that the patient should not be confined in

a room adjoining a water-closet. The puerperal woman was peculiarly susceptible to sewer-gas poisoning, and he could recall two or three cases of trouble after labor in which the bad odors from the neighboring water-closet seemed to offer the only satisfactory explanation of the illness. When labor was concluded there was not likely to be primary decomposition within the uterus, from the fact that, under ordinary circumstances, no air was admitted to the uterine cavity. In the vagina, however, the conditions were somewhat different. There there were heat, moisture, and air, and putridity might possibly result. The practical point in this connection was, that if antiseptic vaginal injections were resorted to when the symptoms first appeared, all trouble would soon vanish. But in cases where the hand or instruments had been introduced into the uterus during labor, those conditions were left which were liable to result in putrid intoxication. Hence the use of intrauterine injections was likely to be of great benefit, and might, perhaps, save the patient's life. If any such procedure was necessary, therefore, it was by all means best to wash out the cavity of the uterus during the labor.

In cases of true septicæmia, where germs (round bacteria) had penetrated into the system, irrigation of the uterus was not of the slightest benefit. It was like attempting to prevent the inoculation of the system with vaccinia, by washing the abraded skin with a sponge after the vaccine virus had once come in contact with the blood. Irrigation was of no use unless there was a "puddle" in the uterus. One injection might, perhaps, do good; but the continuation of them was likely to be injurious. Dr. Lusk then went on to say that when he was in Europe during the past summer, he had visited a number of the principal lying-in institutions there, and when he had inquired whether they now washed out the uterus in puerperal women, the answer was always the same, viz., that if no air had been allowed to enter the uterine cavity during labor, they let the uterus alone. If the hand or instruments had been introduced, on the other hand, they always washed it out. In Vienna it was the practice to use a suppository composed of iodoform and gum tragacanth, and last year the mortality, which for some years previous had amounted to five or six per cent., was reduced to one death in two hundred cases. At Prague the iodoform was not used, but the results lately attained were very remarkable, as out of eleven hundred cases of confinement there had not been a single death from septicæmia. Neither was the intrauterine douche employed there, except under special circumstances, and it was since the indiscriminate use of injections had been abandoned that these good results had been arrived at. These were now reserved for cases in which well-defined indications existed, such as the presence of decaying matters in the uterine cavity. In the main, he agreed with Dr. Thomas as to the use of antiseptics in obstetric practice.

DR. P. F. MUNDÉ said that it had been his fortune to meet with a number of cases of septicæmia, both in hospital and private practice. Of late he had been accustomed to employ local treatment, precisely as in the case of ordinary wounds, and had arrived at the conclusion that this was the proper method of dealing with puerperal septicæmia. He felt that it was his duty to wash out the cavity of the uterus if there was a putrid discharge, accompanied with pus and other evidences of constitutional disturbance. At the same time, he wished to qualify his opinion in regard to the general subject, since in certain hospital cases which he had met with there seemed to be an entire absence of evidences of inflammatory action, and the presence of something altogether different from ordinary septic infection. These were cases in which he agreed with Dr. Barker that sepsis was not the primal cause of the trouble. This was, indeed, only an opinion; but he was willing to stand by it. But, whatever the etiology, he would take the risk of washing out the uterus whenever he met with fever and offensive lochia.

In regard to the method of making intrauterine injections, he agreed with Drs. Hanks and Lusk, that it was better not to change the position of the patient to the edge of the bed, as Dr. Thomas had advised. As to the use of the Davidson syringe, he objected to that on theoretical grounds, as he did not believe in injecting fluid forcibly into the cavity of the uterus. He had met with one case in which it had produced nearly fatal collapse on the ninth day, and he thought there was very considerable risk of injecting the antiseptic solution into the uterine veins. There are considerable dangers met with in the use of intrauterine injections, which he thought Dr. Thomas had not sufficiently emphasized in his paper. After the lochia became pure, he thought it was advisable to discontinue their use, even if the temperature remained high. It was of no benefit whatever to go on with them, and their continued use might perhaps do harm. Like Dr. Lusk, he thought that after septicæmia had gained a foot-hold in the general system, it was of no service to go on making local injections. In one case that he had met with, the introduction of the tube into the uterine cavity was followed by a slight hemorrhage, which was probably the effect of the end of the tube impinging upon the fundus, and after every subsequent injection a little blood came away. If in any case the lochial discharge ceased altogether, it was the duty of the accoucheur to make a thorough examination, when it would probably be found that the uterus had become anteflexed, and the escape of the discharge thus prevented. In such cases the uterus must be straightened and a tube passed into its cavity, when the temperature would probably at once fall. The Chamberlain tube, he thought the most convenient instrument to use; but in the *Boston Medical and Surgical Journal* and other periodicals, cases had been reported in which air had been forced into the uterine cavity through the lateral openings. As to the choice of an antiseptic, carbolic acid had done well enough up to the present time; but in the light of recent researches, corrosive sublimate would seem to be preferable. The objections to washing out the vagina after normal labor, he believed to be valid, and hence he would advise the same treatment in this part as in the uterine cavity: if there were any septic material present, use the injections; but if not, refrain from doing so.

DR. GAILLARD THOMAS was then requested to close the discussion. He rose and said:

Mr. President and Gentlemen: When quite a young lad I was present at a murder trial which made a deep impression on my mind. When the case had been presented the attorney for the Commonwealth, who was a florid and rather bombastic orator, got up and made a

speech of two hours. At the close all were very anxious to hear the counsel for the prisoner, who had a reputation for great eloquence. Judge of the surprise of the audience when he arose and quietly said: "May it please your Honor, the case is closed; I rest it here. The gentleman on the other side has made so able a speech in favor of my client, that I rely upon it for his acquittal." The prisoner was acquitted. I feel very much in this way with reference to the paper of Dr. Barker, to which I have just listened with feelings which I know you, who are his well-wishers, fully share with me—feelings of surprise, regret, and sorrow. Discussions such as this cannot fail to do good, however, for I am a believer in the old Latin adage, "*Ex collisione scintilla.*" And although, in view of the very grievous errors which, according to my distinguished colleague, I have brought before the profession and suggested for its adoption, I may be preferring silver to gold in deciding in favor of speech instead of silence, I feel called upon to say a few words in simple self-defence—that first law of nature.

Our honored President has been very guarded in opening his attack upon my paper, and has seemed to feel concern 'lest its author should take offence at his sallies. Let me assure him and you that it would take a great deal more than such a discussion as this to weaken the ties of friendship which a quarter of a century has cemented between us, or to cause me to take exception to the criticism of one whom I have often in times past encountered in the lists of debate, and have ever found just, magnanimous, and courteous.

But, alas, gentlemen, my adversary has to-night incautiously and, I think, unwisely ventured to use against me that dangerous weapon, a two-edged sword, ridicule. Right mercilessly has he given me one edge; let him beware of the other.

As I saw him draw and flourish this weapon a few minutes ago, I experienced mingled feelings of pleasure and of pain. In a scientific discussion, more especially in a debate which directly and immediately concerns the saving of human life, which at this very moment is being deplorably sacrificed in our very midst, ridicule, elsewhere a powerful weapon, is the poorest and most pitiful of arguments. It is the resort of the weak, not of the strong; and as my adversary used it just now, I said to myself, "he feels himself to be very, very weak; he totters upon his pedestal; 'tis pity that he should feel so; for otherwise that master pen, which so often, in times passed, has enchanted us, would not to-night emit what carries pain to my heart and to the heart of every true friend of his in this assembly; of irritability and of spleen, all of which are so little characteristic of his real nature; otherwise I should not be able to recognize, as all others must do, the utter want of logic, the complete absence of argument, the total neglect of appeal to facts, and the very conspicuous presence of signs of wounded *amour propre*, which, like an unwholesome stream, meanders through his essay."

I shall not detain you long. I have little to say, for Dr. Barker's attack calls for no rebuttal, and demands no argument on my part. I said all that I had to say on December 6, when the original firebrand was thrown down, and picked up by the wrong end by my excellent friend. There are, however, one or two points upon which I must touch to avoid misrepresentation.

Dr. Barker declares the pathology which I have advocated to be unsustained by even the most recent researches of those whom we recognize as guides. He appears to object to the fact that I have not stuck closely to the dicta of our text-books, and hugged to my soul the tenets of a by-gone time, as he has done. This is hardly fair. I strove to follow the advice of Billings when he says, "have something to say; say it; stop when you have said it." Had I had no opinions of my own to offer you; had a practice in a large metropolis and in great hospitals taught me nothing during a period of thirty years, I should not have appeared before you. And let my adversary inform himself upon the recent views of pathologists upon this subject, and he will find it is his views which are effete, not mine which are jejune.

I am very sorry that, owing to the weakness of his position, my adversary has felt constrained to exaggerate to the very verge of misrepresentation, and to attempt to display, under the lurid light of ridicule, my statements with regard to the lochial discharge. As far as I can gather anything certain from his discursive paper, the pivotal idea of Dr. Barker's attack seems based upon the belief that I regard the lochial discharge as a poisonous fluid, which by absorption by abrasions in the genital tract gives rise to puerperal septicæmia. I need not tell you that no such absurd idea ever obtained foothold in my brain or enunciation from my tongue. If his idea be this, he has been guilty of very superficial reading of my paper, and should not so easily have concluded that I was affected by idiocy. Look at my essay, which is now in print, and you will see, what you already appreciate must be the fact, that I stated that the lochial discharge was a material ready to take on those alterations which are effected by micro-organisms of bad character, and which, changing its nature, render it poisonous to the abraded tissues. I believe that you will find that the pathology which I have there offered to you, is merely abreast with the views of the advanced pathologists of Germany, France, and Great Britain. As to the pathology of my adversary, Dr. John Thorburn, of Manchester, England, very justly expressed concerning it, I think, the accepted view of the profession, when, in a foot-note to an article upon "Metria," which appears in the *British Medical Journal* of August 11, 1883, he says: "It would be inexcusable not to make some reference to the very able papers of Dr. Napier in the *Obstetrical Journal* for 1880, on puerperal fever. He, along with Fordyce Barker, defends the old position of a specific puerperal fever *sui generis*. The time limit imposed by our regulations, allows no opportunity of consulting, step by step, such arguments as he advances. I can only say that his invaluable collection of facts produces in one an opinion diametrically opposed to his own."

My critic upbraids me for want of thoroughness, and sketchiness of detail with reference to my description of symptoms. I will merely say, with reference to this, that I intentionally assumed this style, as I was not preparing a lecture for a class of medical students, and my paper was distinctly announced to be one upon "The Prevention and Treatment of Puerperal Septicæmia," and upon nothing else. I cannot but thank him for his kindness in comparing my style, in this sketchy description of symptoms, to that of Byron and Humboldt (I

believe these were the authors with whom he compared it), but, alas! as I recall the passages to which he alluded, I am pained to confess that the similarity of style does not strike me as forcibly as it does my partial friend.

Here let me draw the veil of pitying silence over the unfortunate allusion to the squib of Stepney, and the relics of the Hotel de Cluny! We stand to-night upon ground consecrated to science by the dignified fathers of the New York Academy of Medicine, who have now passed away. We stand face to face with the terrible mortality which marks puerperal fever at this very moment.

And now, Gentlemen, a few words as to the prevention and treatment of puerperal fever, which is the only legitimate subject before us for discussion this evening; the only theme which should not at the very commencement of these exercises have been rigidly ruled out, as irrelevant, by our President.

How difficult is it in a large body like this to keep the discussion properly directed to the point at issue! I hope that those who have discussed my paper will pardon me for saying, that we have heard a great deal to-night in way of repetition of what my paper contained as to pathology, a great deal about tubes, and the number of holes which should be made in them, and diverse opinions as to whether or not a suppository of iodoform should be put into the vagina, and small doses of ergot given for a week or so post-partum; but these are non-essentials and hardly worthy of the valuable time which has been given to them, when so much of greater importance remained to be considered. The crucial questions, Fellows of the Academy, which are before you to-night, are these: 1st. Are you to look upon puerperal septicæmia as a poison due to the development of micro-organisms, and are you by every means in your power to guard against the contact of these with the genitals of the puerperal woman? And 2d. When the disorder is developed is it best for you to keep your patient semi-narcotized and quininized, while the distended abdomen is covered with stupes of turpentine or poultices, and await the result, as has formerly been done; or are you to seek to destroy the septic germ which has invaded the genital tract, by local application? These are the great questions; the other points are non-essential ones, and, although important in some respects, sink into insignificance when compared with these.

Take, for example, the first of my suggestions as to the cleansing the lying-in room and applying antiseptic solutions to its walls and floors before labor sets in. This seems to appear to some like one of the labors of Hercules; and a very valued friend of mine, one of the most eminent obstetric professors of this city, seems so firmly to keep his eyes fixed upon it as to allow it to draw his gaze away from others which are of tenfold its value. Now, Gentlemen, what is really the difficulty of doing this thing? In the cottages connected with the Woman's Hospital it is regularly done whenever a new patient comes in for laparotomy, which is on an average once a week; and whenever I operate in private practice, let the operation be as trivial as it may, I always insist upon its performance. A scrubber—and there are many women in New York who make such work a business—takes up the carpet and sends it to the Naphtha Cleaning Works, or replaces it by rugs. She then scrubs the floor and furniture with a solution of carbolic acid or the bichloride of mercury. Then, covering a broom with a towel, she stands upon a pair of steps, and, dipping this in a bucket, she wipes off the walls and ceiling. The whole work of cleansing a chamber occupies a few hours. Dr. Lusk has said that he has never seen any good come from scrubbing furniture with an antiseptic solution. Agreed. I have never seen it do any harm, and until I do so, I shall feel that it is safer to resort to it. But, Gentlemen, I am not particularly enthusiastic about this cleansing of the chamber, nor do I regard it as by any means essential. If any gentleman prefers to have his patient confined in a dirty room rather than a clean one, let him do so by all means. I do not gainsay it. If I need any defence for having pressed the claims of cleanliness in this regard, let it be found in the fact that he who offers rules for a system, must aim high, not low; that, aim as high as he may, many will fall below the standard; that if a low level be assumed, no one will go above it and take a higher.

My second suggestion for prevention, has reference to complete change of clothing and the taking of an antiseptic bath by doctor and nurse, before taking charge of a lying-in woman, if they have knowingly been exposed to the effluvia of septicæmia, erysipelas, scarlet fever, typhus, or any similarly contagious affection. Will any one object to this as unnecessary or impracticable? I think not. Yesterday at 4 P.M., I saw in Stamford, a very bad case of puerperal septicæmia; this afternoon at 3, I performed Tait's operation upon a very important case, which could not be delayed. I ventured to do this only under these circumstances: this morning I took a bath of hot water strongly impregnated with salt, and after it shampooed my hair and beard thoroughly with a saturated solution of boracic acid, scrubbed my hands thoroughly, by means of a nail-brush, with a solution of the bichloride one to one thousand, and changed every article of clothing which I had worn at the moment of exposure. The trouble was not great, nor was the process a disagreeable one. It may have done no good whatever, but I feel sure that it did no harm, and it certainly quieted my conscience and gave me a feeling of comfort that I could have obtained in no other way.

My third suggestion was that during labor, a warm antiseptic injection should be administered to the patient by the nurse, about every four hours, and that a towel wrung out of this warm solution should be laid over the vulva. Who objects to this? "If any, speak, for him have I offended." It is very soothing to the patient, and it is difficult to see how she could be injured by it.

My fourth suggestion merely relates to cleanliness of the hands on the part of doctor and nurse. The propriety of this I shall not discuss.

No one will quarrel with my fifth and sixth, which merely require the physician to attend intelligently and faithfully to the performance of the third stage of labor, and the examination for, and closure of, wounds about the vagina and ostium vaginæ.

I now come to the seventh suggestion, the use of vaginal injections every eight hours, beginning eight hours after delivery. The arguments which have been brought up against this practice since I read my paper, have had great weight with me. I confess I feel less

firm in my conviction upon this point than I did, and that in future I shall examine the question carefully before I determine to adhere to my plan. You may ask, Why this change of opinion? My answer is that I strive to mend the fault of yesterday with wisdom of to-day.

The rest of my rules will be so certainly agreed in that I cannot question the concurrence of all, even of the eminent gentleman, our President, who regards my efforts as so hurtful to progress and so dangerous to the community to whose medical guides I have made appeal.

A few words now, before closing, upon some of the means which I have suggested as to treatment. With reference to my present views upon the use of cutaneous refrigeration for the controlling of high temperature, however produced, and in the course of whatever disease occurring, I would—after a very extensive experience—say this: Were the laws of my country to prohibit a resort to this method, I would be unwilling to continue the practice of my profession, for I could not do so without relinquishing what I sincerely believe to be one of the most valuable therapeutic resources at the disposal of the physician.

In regard to intrauterine injections, if I have expressed myself in such a way as to allow it to appear that I resort to them with very little provocation and upon all occasions when hyperpyrexia supervenes after childbirth, no impression could be more erroneous. No one could have striven more than I have done to keep within proper bounds, the indiscriminate use of this valuable but dangerous resource. Let me illustrate my feeling with reference to this subject in the following way: I believe that the operation of trachelorrhaphy, as introduced by my friend Dr. Emmet, is one of the greatest advances which a quarter of a century has seen in gynecology. I believe that at the present moment it is doing a great deal of harm on account of its indiscriminate and too frequent performance; many seeming to believe that every woman who bears a child requires a resort to it. Does this militate against the great value of the procedure? Not at all, "*Uti sed non abuti*" might well have been written over its original description, as in olden times it was inscribed upon the case which held the lancet.

My friend, Dr. Barker, must here allow me to offer him a most full and sincere apology for not having accorded to him in my paper the credit which was his due in connection with the introduction of intrauterine injections into obstetric practice. I know that he will freely forgive me when I state that the omission was due to ignorance on my part of the facts which he has stated to-night, and not to any intentional neglect.

Dr. Mundé has expressed the opinion that I have not sufficiently guarded my readers against the dangers of intrauterine injections. As I recall my statements, I cannot but feel that he is in error upon this point, for I certainly strove to the utmost of my capacity so to depict these dangers as to put every man upon his guard concerning them.

I have not been surprised to notice, among other criticisms of the preventive measures which I have suggested, a tendency on the part of some to ignore the necessity for them, especially in private practice. That this would in all probability be done, I suggested in my paper, and I came here this evening prepared to use some statistics which would invalidate this position. I shall not use those which I brought, however, but employ, in their stead, some which have been offered by the speakers of this evening. Dr. Hanks declares that more than two hundred and fifty women died from puerperal septicæmia in this city last year; that is, two hundred and fifty to a million inhabitants. The United States probably contains, in round numbers, forty million inhabitants, which would give us ten thousand deaths in one year, and in twenty years, which is about the average childbearing time of women, two hundred thousand deaths. Surely, this looks as if something should be done to lessen the mortality of this disease. Does the plan which I have suggested accomplish this result? Let Dr. Lusk answer. He has just told us that in Prague, before a similar plan was adopted—that is, before antiseptic surgery was introduced—they lost five per cent. of hospital puerperal patients by septicæmia; since then eleven hundred women have been delivered without a single death. I hope that I am correct in my quotation of Dr. Lusk; I think that I am.

And now methinks I hear a whisper to this effect: these are the statistics of hospitals; the disease must be rare in private practice, for has not Dr. A. told us that he, out of 500 cases, has had no death; Dr. B. that, out of 1000, he has had none; and Dr. C. that, out of 1500, he has met with only one. Patients are constantly dying from this cause in private practice, nevertheless. It is now just two months since I read my paper, and during that time I have been called to five cases of puerperal septicæmia, four of them, at least, in the higher walks of life, and all four of the most desperate character.

I prefer to state with whom these patients were seen and I feel sure that my colleagues who called upon me will appreciate my motive, and pardon me for doing so. The first case I saw with Dr. Glück; the second with Drs. Hutchison, Crane, and Paine, of Brooklyn; the third with Dr. Lyons, in which suppurative synovitis and abscesses had followed a miscarriage; the fourth I was called to by Dr. Lowenthal, but could not attend; and the fifth I saw yesterday, in Stamford, with Drs. Janeway, of New York, and Phillips and Hurlburt, of the former place. I have ventured to give the names of the practitioners with whom I saw these cases to prove that they occur even under the most favorable circumstances as to social surroundings and medical care.

And now, Gentlemen of the Academy, let me thank you for the kind and courteous attention which you have given me. It is that attention and that courtesy which have emboldened me to detain you so long. I feel very sure that you will give full credence to two statements which I make in bidding you good-night: First. That I have no wish to be dogmatic and uncompromising in reference to the rules which I have suggested for the prevention and treatment of puerperal septicæmia. Second. That if venom has seemed to flow from my tongue it has not reached it from my heart, which has been entirely free from it; and that if I have seemed to strike too trenchant blows at the learned head of our President, I have struck purely in self-defence at one for whom I would yield to no man in respect, admiration, and affectionate regard.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 22, 1884.

THE PRESIDENT, R. F. WEIR, M.D., IN THE CHAIR.

HABITUAL DISLOCATION OF THE ULNAR NERVES —MYOSITIS.

DR. F. LANGE presented a patient, a violinist, who, about a week ago, immediately after more than his usual amount of labor, began to suffer from a severe pain in the muscles of the right forearm, near the elbow-joint, and especially very near the internal condyle. The severe pain lasted only a short time, but the pain did not cease entirely; increased during the next two days, after repeated use of the arm, and on the third day was again so severe that every movement at the elbow-joint was impossible, and the patient suffered intensely. He was under medical treatment for a number of days, and he called to see Dr. Lange last Saturday, when it was noticed that there was some swelling corresponding to the muscles of the forearm, which took their origin from the internal epicondyle, and there was a very tender spot at the end of the ridge through which the ulnar nerve passes. Closer examination determined the existence of luxation of the ulnar nerve between the olecranon and the internal condyle at every attempt to flex the forearm. The nerve could be traced quite distinctly, and rolled freely under the thumb and finger, so that in a semiflexed position it could be dislocated around the protruding point of the epicondyle. The most painful point, however, was where the nerve entered the muscles. In the left arm also the ulnar nerve could be easily moved under the thumb and finger, and the question arose whether the difficulty in the right arm pertained primarily to the nerve or to the muscles. Dr. Lange thought, however, that the case was one of myositis, involving the muscles which have their origin in the region of the internal condyle, and thought perhaps also that the sheath of the nerve had become involved. There were no peripheral alterations pointing to a lesion of the nerve itself.

EXCISION OF THE ELBOW-JOINT.

DR. LANGE also presented a patient in whom he had excised the left elbow-joint nine months ago. She was presented for the purpose of exhibiting an apparatus—described already some years ago—which he had used after this operation with considerable advantage, and which he regarded as useful, especially in those cases in which a great deal of bone has been removed and the new formation is comparatively small, and also where a great deal of abnormal mobility exists. The idea involved in the apparatus is that some slipping of the bones be allowed in such a way that the bones of the forearm are somewhat forced backwards, and an adjustment effected which imitates their physiological apposition. At the same time the joint, by means of rubber strings, is kept in semiflexion. The exercises are done by trying to keep a weight grasped with the fingers, and not allowing it to extend the forearm. In this way the point of support is transferred to the attachment of the rubber strings, a lever action takes place, by which the bones at the forearm are still more brought into coaptation. The weights must be chosen so that they are slightly too heavy, and slowly pull the arm into an extended position. Active extension alone is practised in applying weaker artificial flexors. He thought that after the apparatus had been worn for a year or more, functional ability of the forearm would be very much improved.

DR. J. C. HUTCHISON inquired whether the motions of the forearm without the apparatus improved any.

DR. LANGE said there was improvement, but it was very slight, and the movements of the forearm were very uncertain without the apparatus, which had been worn for a very short period of time, she not having had any orthopædic treatment for a number of months.

DR. J. L. LITTLE referred to a case in which he excised the elbow-joint, and the instrument-maker constructed a similar apparatus, which had enabled the patient to use her hand ever since she began to wear it. While wearing the apparatus she was able to accomplish considerable work, but when the apparatus was removed the arm was perfectly useless and hung by her side. The apparatus did not permit of the slipping of the bones, as did that exhibited by Dr. Lange.

DR. H. B. SANDS read a paper on

INTERNAL ŒSOPHAGOTOMY.

(See THE MEDICAL NEWS for February 9, p. 145.)

DR. POST remarked that Dr. Sands had suggested, as prophylactic treatment, that dilatation be commenced a week after the injury. He would suggest that a week would be rather early, and that two or three weeks would be better, as it is only after the sloughs have separated and the reparative process has become well established that the contraction begins to take place.

DR. SANDS remarked that his patient was about the house and apparently in pretty good health four days after the injury; and he would prefer to give, as a rule, a too early rather than a too late period.

THE PRESIDENT remarked that it had been his good fortune to witness the operation of Bergmann described in the paper, in which the gastric fistule made for the relief of a strictured œsophagus was subsequently closed, after the stricture had been sufficiently dilated. It certainly was a unique and remarkable case.

One point in connection with the paper he thought worthy of remark was the omission of continuous dilatation. He had not had any personal experience with cicatricial strictures as tight as Dr. Sands had cited, but he had had some experience in the treatment of quite narrow malignant strictures. Recently, in one instance, a No. 18 soft catheter was kept in position three weeks prior to the death of the patient, and with great comfort and improvement in the size of the strictured portion, though nourishing the patient was, in the case, the only point aimed at. He was led to adopt this method of treatment by reading an article by Krishaber, who had employed continuous indwelling of the catheter for such lengths of time; and in one instance the instrument remained in position for one year without any detrimental result. The comparison with reference to dilatation was often made between the urethra and the œsophagus, but erroneously; for in the former there is present an irritating or septic urine. Dr. Weir thought it had been shown by Krishaber's cases that the œsophagus bears continuous dilatation better than the urethra does; and the food, being carried inside of the tube, cannot produce irritation. He would therefore, in cases of cicatricial contraction, first try the method of dilatation, before resorting to operative procedures.

REMOVAL OF FOREIGN BODIES.

DR. HALSTED presented several foreign bodies with brief histories of the cases from which they were removed.

Case I.—A piece of fibro-cartilage removed from the œsophagus by external œsophagotomy, at Ward's Island. Hungarian, æt. 33, July 23, 1882, swallowed, at his dinner, a piece of food which became arrested in his œsophagus a little below the cricoid cartilage. The resident physicians were unsuccessful in their attempts to remove it with forceps. They obtained, however, a fragment which, submitted to microscopical examination, proved to be fibro-cartilage. Patient is said to have experienced great difficulty in breathing for several hours, and then to have become quite tolerant of the foreign body, but was unable to swallow even liquids.

July 25.—Foreign body indistinctly definable by palpation of neck, is believed to be lodged in œsophagus just above sternum, projecting more to the right side than to the left. An incision, extending from middle of thyroid cartilage to the interclavicular notch of sternum, is made parallel with the anterior border of the sterno-cleido-mastoid muscle. The oblique jugular vein drawn towards median line. Middle thyroid vein, in upper angle of wound, doubly ligated and divided. Common carotid artery crossed by omohyoid muscle rises up into view.

Foreign body readily mapped out through œsophageal walls, and over it is stretched the recurrent laryngeal nerve. An incision one and a quarter inch is made into the œsophagus, parallel with and posterior to the nerve and the foreign body, measuring one and a half by one inch, removed with a vulsellum forceps.

Wound in œsophagus united by sulphurous acid catgut, and the integument by silk sutures. An iodoformized peat dressing applied. A few days later patient was clandestinely served with blackberries, by missionaries to the island, which interfered with union by first intention, but otherwise did not retard his prompt recovery.

Case II.—Three calculi, each with a portion of a soft catheter as a nucleus, removed from the bladder by lateral lithotomy at one operation.

The patient, a Finn about thirty-five years old, had been in the habit of evacuating his paralyzed bladder with a soft catheter. One day the catheter broke off in his bladder, and a piece, believed to be two or three inches long, was left behind. He subsequently regained the power of his bladder, and applied, six or eight months after the mishap, to Ward's Island for relief of painful and frequent micturition. A stone was detected by Thompson's searcher. On consideration of the history it was believed to be advisable to practise the cutting operation. Patient had such a short perineum that a finger introduced into the bladder could ascertain the number and shape of the stones. These were seized so carefully with the forceps as not to be crushed and removed. The patient's convalescence was somewhat protracted because of a cystitis perpetuated by a few fragments which he eventually passed per urethra. Each calculus contains a piece of the catheter, its point being distinctly demonstrable in one of them.

Case III.—A portion of a bullet removed from the diploë and cranial cavity.

Mr. H. W. G., æt. 52, was admitted to Chambers Street Hospital, May 9, 1883, for a self-inflicted pistol-shot wound of the head.

Examination. Small circular scalp wound on right side, two and one-half inches below sagittal suture, and one inch in front of external auditory meatus. Normal reflexes and no paralysis—intellect perfectly clear.

Operation. Crucial incision through scalp. External table depressed, and at bottom of depression a hole one-quarter inch in diameter, and about one inch behind bullet wound in soft parts. A probe passed obliquely backwards through the hole detected the foreign body, which was not visible. Thereupon certain fragments of external table were removed, and the bullet revealed lying between the two tables, and projecting somewhat into the cranial cavity—upon its extraction a slightly depressed fragment of the inner table was withdrawn. The wound was dressed antiseptically, and closed with a continuous catgut suture.

Union took place by first intention throughout, except where the incisions crossed one another, viz., at the point of entrance of the bullet, and here there was a very slight necrosis of the approximated corners of the flaps.

The bullet had split upon the outer table of the parietal bone; one fragment entered the diploë and cranial cavity, as described, and the other passed through a mirror, and was found behind the bureau.

DR. HUTCHISON said that some time ago he presented a urinary calculus to the Society, which had for its nucleus a loop of silver wire. The patient had a urethro-vesical fistule which had been closed with silver wire sutures, and he (Dr. H.) was reported to have stated that a house surgeon who had been directed to remove the sutures, overlooked one, which fell into the bladder and formed the nucleus of the stone. This was an error. Dr. Hutchison said that he had himself removed the sutures, and was responsible for having failed to remove the one which entered the bladder.

CORRESPONDENCE.

THE EXTERNAL USE OF THE OLEATE OF ACONITIA.

To the Editor of THE MEDICAL NEWS.

SIR: Allow me to add some supplementary statements and suggestions to my note on the external use of the oleate of aconitia, in reply to numerous communications direct and by letter. The strength of the solution used was 2 per cent. of the alkaloid, so that one minim contained one-fiftieth of a grain. Great care is requisite in securing a pure salt, and the least superheating in combining with the oleic acid destroys its value. My own preparation was made from the imported Duquesnel's "nitrate of aconitia."

Further, I am in possession of no facts which would lead me to suppose that the drug would be of any, even the slightest, value in cases of *peripheral spasm.* Several of my correspondents have spoken of disappointment following its use in cases of *facial spasm* and a number of cases of *spinal accessory spasm.* All reasoning from known facts would lead me to conclude that such a result would only be obtained in an advanced stage of poisoning by the drug. The sensations of pricking,

formication, and numbness, followed immediately by relief, and felt within six seconds after the application, seem to demonstrate that its therapeutic action in the cases referred to is confined to *terminal sensory filaments*. It is a fact, pregnant with suggestions, that in one case in which it was of most signal service, the pains were induced by a large tumor stretching the right brachial plexus, which was enveloped by a mass of hard inflammatory tissue.

I would suggest the further use of the oleate of aconitia as a relief for the burning pains and hyperæsthesia of *neuritis*, and for the distressing pains in those cases of *cancerous growth* involving nerve-trunks, whether in the spinal canal or out of it; in cases of neuromata, single or multiple, especially the multiple subcutaneous form. It also holds out a very fair prospect of relief for those miserable sufferers from *causalgia* (burning pain) in its aggravated forms, symptomatic of *neuritis*, usually traumatic. Very truly yours,

HOWARD A. KELLY, M.D.

PHILADELPHIA, 249 S. SEVENTEENTH STREET.
January 26, 1884.

SOME RECENT INVESTIGATIONS ON GERMS.

[THE following letter has been received at this office. The author, Herr Riechschwamm, does not belong to our staff of special correspondents, nor is he personally known to us. He signs himself, "First Assistant to Dr. Hahn," but upon reference to the last volume of the *Mittheilungen aus dem Kaiserlichen Gesundheitsamte*, Magdeburg, we do not find his name among the Hülfsarbeiter. These facts, together with the very remarkable results of the investigations he reports, have led us thus to inquire into his trustworthiness. We have felt it incumbent upon us, in publishing his letter, to make this prefatory statement, rather than to withhold information of these latest researches, which are certainly calculated to arrest our attention, even if they do not immediately commend themselves to our unreserved acceptance.—ED.]

MAGDEBURG, January 31, 1884.

To the Editor of THE MEDICAL NEWS.

SIR: I have thought that some account of the recent discoveries in regard to bacilli might interest readers who are remote from the great radiating centres of constructive science. The latest of these discoveries is even yet spoken of here with caution, but by the time you have printed this, it will have revolutionized one branch of physiology, and produced an evolution of novel ideas, the final results of which not the boldest can predict. But before outlining for your readers a discovery which I am privileged to communicate by permission of Professor Coccischlächter, and before it has been fully published at home, it may be well to describe the Krankheitenursprungsanstalts — Museum of Bacilli — collected by the Herr Oberprofessor Keimerzeurger von Verdammtnarrburg.

This has been done at the cost of more than one life upon the altar of science. The museum is a room about thirty feet square, with double walls of glass, between which circulates water kept at a temperature of 30° C. by three gigantic thermostats, which are so accurate that the heat does not vary the one-fifteenth of a degree. Ranged along the sides, exposed to air or under glasses, are hundreds of half potatoes, on which grow various bacilli; of late, however, boiled cabbage is said by Keimerzeurger to answer better. Certain specific cocci flourish on the Beta altissima or mangel wurzel, but as to this choice of cultur gartens more is to be said. To walk through this museum with the Herr Professor Keimerzeurger is interesting. Before entering, a mask is given you, and a bottle of condensed oxygen, so as to enable you not to inhale the atmosphere loaded with germs. In tones muffled by the need to speak within the mouth-piece, you learn that to the left is a tubercular potato, its surface gray with the potencies of countless deaths. Near it the bacillus of gonorrhœa flourishes on the cut surface of the succulent beet, beside the ruddy germs of syphilis. Scarlet fever infests this potato, diphtheria that. The new bacteria of pneumonia flourishes on a boiled watermelon; and glanders, cholera, smallpox, and hydrophobia spread in tiny greenish growths over the little gardens of gelatine. For a moment, in my interest, I displaced my mask. The professor instantly seized me and hurried me from the room. "What a risk!" he said; "my last assistant did as you did, and died in seven days of acute phthisis, with symptoms of hydrophobia and whooping-cough, combined in horrible equality." I did not desire to reënter this box of Pandora. In adjoining apartments of less size are the experimental cultivations, those which are still in doubt. Among the most interesting is the micrococcus of gout, found to flourish best upon gelatinized turtle soup.

A most striking practical result has grown out of some of Coccischlächter's and Keimerzeurger's later researches. They have been able to show that the bacterium of colic flourishes on the green apple, which accounts for the gripes experienced by youthful gourmands. But far more remarkable is the fact that certain micrococci and bacteria die, as proved by Coccischlächter, in some culture materials, and thrive, as shown by Keimerzeurger, on others. Thus the tubercle bacilli flourish on boiled cabbage (Keimerzeurger), but perish on moist sauer-kraut (Coccischlächter), so that by a persistent diet of the latter article they have been able to saturate some of their devoted assistants up to the point of insusceptibility, a discovery which will, we trust, put an end to the cavils at the failure of these researches to yield practical results.

Most startling of all is Herr Keimerzeurger's latest result. He has been able to show that the inconvenient monthly sickness known as the menstrual flow is a non-essential of female life, and is due to a peculiar bacillary growth. It is at once and for many months destroyed by the growth of the bacterium virilis, long misapprehended as the spermatozooid. This latest discovery has been received with derision in France, but Hahn has given it his support, and in my next I shall report his confirmatory experiments. RIECHSCHWAMM,

First Assistant to Dr. Hahn.

NEWS ITEMS.

PORTLAND, MAINE.

(From our Special Correspondent.)

ALUMNI ASSOCIATION OF THE GRADUATES OF THE MAINE MEDICAL SCHOOL.—For some months past there has been a growing sentiment among the graduates of

the Medical School of Maine in favor of the organization of an association, to renew old associations and advance the interests of medical education in this State. January 30th, some twenty or more, from all sections of the State, met at Waterville, and organized under the name of the "Bowdoin Medical Alumni Association." A constitution was adopted and officers elected. Any person on whom a medical degree has been conferred by Bowdoin College is eligible to membership on paying the required fee, provided that his character and professional standing be satisfactory to the executive committee. Officers are to be elected at the annual meeting, which will occur during the week of the close of the school at Brunswick. Expenses are to be met by assessments, but no money of the Association can be used to pay for refreshments, a clause which may be a good test of future interest in the Association on the part of members.

Officers were elected as follows:

President.—Frederick C. Thayer, M.D., of Waterville, Class of 1867.

First Vice-President.—Sumner Laughton, M.D., of Bangor, Class of 1834.

Second Vice-President.—R. D. Bibber, M.D., of Bath, Class of 1871.

Secretary and Necrologist.—Charles D. Smith, M.D., of Portland, Class of 1879.

Treasurer.—Frederick H. Gerrish, M.D., of Portland, Class of 1869.

The next meeting will be held at Brunswick during the last week in May next. A banquet will be served, and an address delivered by Dr. A. J. Fuller, of Bath, Class of 1841.

Much enthusiasm was manifested by those present. Many were present from distant parts of the State, the eldest, Dr. S. M. Bradbury, of the Class of 1831, travelling the greatest distance. Dr. Thayer, of Waterville, reported that circular letters had been sent to nearly four hundred graduates, and replies expressing interest and coöperation in the movement received from a very large proportion of this number. The friends of the School see in this movement renewed efforts to keep up its present good name, and the indications of hearty aid and support in definite shape from the physicians it has educated during its sixty odd years of existence.

MONTREAL.

(From our Special Correspondent.)

Doctors at Law.—The case of Dr. Severin Lachapelle *versus* Dr. F. W. Campbell *et al.*, at present before the Superior Court in this city, is exciting a good deal of interest in the profession. About two years ago an editorial appeared in *L'Union Medicale*, entitled "Fiat lux," in which it was stated that some four or five French Canadian medical students had received a private examination from the faculty of one of the medical schools of Montreal, and had received certificates which would be accepted in the United States. This, of course, is contrary to the law of the Province, which places the supervision of the college examinations in the Provincial Medical Board, which body appoints assessors to be present at, and who report on the character of, the examinations. In the editorial enough was said to make the members of the Medical Faculty of Bishops College feel that their institution was referred to; and a criminal action for libel was brought against the proprietors of *L'Union Medicale*. The Grand Jury threw out the bill, and the present action is brought by the editors of that journal against Dr. Campbell and other members of his school for damages alleged to have been sustained by bringing a criminal action against them.

There can be no doubt that the editors of *L'Union Medicale* did not exceed their normal privileges in the editorial "Fiat lux," believing, as they did, in the genuineness of the certificates possessed by the young men, which were signed by Dr. F. W. Campbell as Registrar of the Bishops College School. But it appears that none of the members of this school know anything of such a private examination, and the certificates are believed to be forgeries. If this is the case, it is a great pity that the matter could not be amicably arranged, as both parties have been the victims of a fraud. Some advantage may come of it, if the perpetrators of the forgery can be discovered and punished.

Preliminary Education.—At the last meeting of the Board of Governors of the College of Physicians and Surgeons of Quebec (the Provincial Board), a committee was appointed to confer with the heads of schools and colleges, to arrange, if possible, that the young men presenting themselves for the preliminary examination for permission to enter upon the study of medicine, should be better prepared, and to discuss the causes of the wholesale rejections which have taken place during the past two years. An important conference on the subject took place on the 24th, and the matter was fully discussed. The general opinion was that the examination was not too stringent, but that in certain branches the French students, and in others the English students, were not sufficiently grounded, and it was agreed that for the future greater attention should be paid to these subjects.

The British Association for the Advancement of Science.—The list of members who have signified their intention of coming out to the Montreal meeting has been received. It includes the names of nearly sixty medical men, among whom are some of the most distinguished members of the profession in Great Britain. Bastian and Schäfer, of University College, London; Struthers and Stirling, of Aberdeen; Foster and MacAlister, of Cambridge; McKendrick, of Glasgow; Morely, of Oxford; A. Milnes Marshall, of Owens College; Cheadle, Pye-Smith, Protheroe Smith, Heywood Smith, W. B. Carpenter, George Harley, Arthur Durham, William Wood, and F. J. Mouat, of London; Lawson Tait, of Birmingham, and many others are expected.

The Canada Medical Association meets in August, in Montreal, a few days before the British Association, and it is hoped that a number of these gentlemen will be present.

Yellow Fever Notes.—Sanitary Inspector Burgess, stationed at Havana, reports four hundred and eighty-two deaths from all causes during the month of January, thirty of which were from yellow fever, six from typhoid fever, nine from pernicious fever, and two from diphtheria. Of those who died from yellow fever, twenty-

five were among the shipping and private individuals in the city, the remaining five among the army and navy.

During the same month last year there were fourteen deaths from yellow fever. An absence of hurricanes and high winds is noted.

His weekly reports show that he disinfects all vessels taking on or discharging cargoes at suspicious wharves, if bound to any port in the United States south of Hatteras.

Reports from Rio de Janiero state that smallpox is more fatal just now than yellow fever. For the two weeks ending January 5th there were eighteen deaths from smallpox, and but fourteen from yellow fever.

THE PUBLIC HEALTH COMMITTEE OF THE HOUSE.—At the last meeting of the Public Health Committee of the House of Representatives, the Secretary of the National Board of Health made a wordy personal attack upon the Surgeon-General of the Marine-Hospital Service, and the Executive Committee of the National Board apparently concurred in his charge that Surgeon-General Hamilton had been "injudicious, unskilful, and unsuccessful in his quarantine work," and that "in his efforts to control public and official opinion he had been guilty of misrepresentation."

Surgeon-General Hamilton, not having been invited to appear before the Committee, was not present, but we are informed that he will claim the right to a hearing, to justify the action of the Marine-Hospital Service.

CHOLERA.—Fifty-four deaths from cholera occurred at Calcutta during the two weeks ending December 15, 1883.

VIVISECTION IN GERMANY.—The *Deutsche med. Wochenschrift* for December 19th announces that the Prussian Government, in anticipation of the renewal of the discussion on the question of limiting the practice of vivisection, which is to take place during the present session of the Parliament, has issued a circular to the medical faculties of all the Prussian universities, requesting a statement of their opinions on the question. This calls to mind the fact that on the occasion of the interpellation which took place last session, a distinguished physiologist resolved to exhibit to the ministry, in a striking and graphic manner, the relation which vivisection bears to the progress of physiology. Taking the last edition of *Hermann's Manual*, he scored all the well-founded facts which could never have been firmly established without the aid of vivisection. When he had done with the book, it very much resembled in appearance a liberal political journal which had been submitted, in the worst times, to a Russian censor—the passages struck out, exceeding in number those that were allowed to remain in.—*Med. Times and Gazette*, January 19, 1884.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending February 2, 1884, indicate that consumption, erysipelas, and remittent fever have increased, and that diarrhœa, intermittent fever, typhoid fever, and typho-malarial fever have decreased in area of prevalence.

Compared with the average for the month of January in the preceding six years, neuralgia was more prevalent, and diphtheria, rheumatism, typho-malarial fever, bronchitis, scarlet fever, consumption, pneumonia, and remittent fever were less prevalent in January, 1884.

Including reports by regular observers and others, diphtheria was reported present during the week ending February 2, and since, at eighteen places, scarlet fever at thirteen places, and measles at seven places.

NOTES AND QUERIES.

AIR IN THE VEINS AS A CAUSE OF SUDDEN DEATH AFTER LABOR.

To the Editor of THE MEDICAL NEWS.

SIR: In THE MEDICAL NEWS of November 10, 1883, is an editorial entitled, "Air in the Veins as a Cause of Sudden Death in Puerperal Women." It having been my misfortune to attend a young lady a short time previously, whose sudden death had created a gloom and cast a shadow over the community by whom she was universally beloved, and not being able to offer any satisfactory explanation of the causes of her death until I read the article alluded to, I have thought a short description of the case might prove of interest to some of your readers.

This young lady had been under my care from the beginning of her pregnancy, and there had been nothing unusual or any symptom to indicate any untoward termination of the pregnancy. Her general health had been good, her figure, as far as I could judge externally, was perfect, and there was no reason to anticipate the disastrous result. I was called to her about two o'clock on the morning of the 29th of August, and upon examination found the bag of waters unbroken, and the labor proceeding as naturally as possible. The membranes were ruptured after they had done their part, and the child was born about five o'clock A. M. The placenta was not retained more than a half hour, and was thrown off under the influence of ergot, which contracted the uterus firmly.

Three-quarters of an hour afterwards, whilst I was superintending the dressing of the child, the mother called to me, and said she felt very faint and badly. Immediately the idea of hemorrhage occurred to me, and I placed my hand upon the uterus, which, to my surprise, I found firmly contracted, so that there could be no hemorrhage, and upon vaginal examination could detect none. Upon removing the pillows, and administering stimulants, she apparently revived, and said she felt better. In the course of a half hour the same thing recurred, and although I administered stimulants freely, both hypodermatically and by the mouth, she did not revive, but gradually sank, her pulse becoming weaker and weaker, her breathing more and more oppressed, the lividity of countenance increasing gradually as the heart failed, until, eventually, about half past nine o'clock, she sank, unconsciously and peacefully, into the arms of Death—apparently as if some power had been controlling and compressing the heart until it could no longer act, but quietly ceased to struggle. There were no convulsions, no hemorrhage except that which is met with in every case of labor, but only a gradual cessation of the impulse of the heart.

I could arrive at no definite conclusion as to the cause of death, and was unable to answer the question when asked me, "Why she had died?" I was aware of Dr. Meigs's "Heart-clot Theory," and also of the symptoms of thrombosis; but, as you state in your editorial, "these are causes of rapid, rather sudden death," and I could not satisfy myself that those causes entered into the case; in fact, until I read your article, I was at a loss. Since reading it, I feel confident that the condition you describe is the explanation of the death; and I write this in the hope that it may be of assistance to some one similarly circumstanced. I have been particular in describing the symptoms, so that it may be easier to recognize the trouble, even if we are unable to render any assistance.

Yours respectfully,

R. B. HANAHAN, M.D.

WINNSBORO, S. C., February 5, 1884.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIV. SATURDAY, FEBRUARY 23, 1884. NO. 8.

ORIGINAL LECTURES.

ON DISEASE OF THE KNEE-JOINT.

A Clinical Lecture
Delivered at the Bellevue Hospital Medical College, New York.

BY LEWIS A. SAYRE, M.D.,
PROFESSOR OF ORTHOPEDIC SURGERY IN THE COLLEGE

(Reported by Edward Develin, M.D.)

GENTLEMEN: This morning I desire to call your attention to disease of the knee-joint. There are, in all, fourteen ligaments connected with this joint—your Professor of Anatomy having doubtless demonstrated the same to you. The bony structures assisting in the formation of the joint are the femur, tibia, and fibula, together with the patella—the whole being lined by a synovial membrane.

We shall first take up synovitis. This can be caused by constitutional affections alone, as gonorrhœa, rheumatism, etc.; or it may be induced locally by a blow, wrench, or cold. If it is acute, and the joint filled with fluid, and the patella elevated, giving fluctuation, by percussion you can get a click of this bone upon the femur, as a rule. If, however, the effusion is not very great, you will fail to get this click; but you will be enabled to detect the peculiar fluctuating feeling upon either side of the patella. You will remember that under the patella there is a bursa, and another under the tendon of the quadriceps muscle above the patella, and yet another external to the patella. These I specially call your attention to, as they are of vast importance and significance: for you may mistake a disease of these bursæ for disease of the knee-joint itself. Between the bursæ and the knee-joint we find quite a mass of fat. It is, however, well to remember that disease of these bursæ may also involve the knee-joint.

Now, in synovitis of the knee-joint resulting from constitutional causes, if it be from rheumatism, as a matter of course you diagnosticate the case from the manner in which the pain changes from place to place. But you must also think that, perhaps, in addition to the synovitis, you may have an osteitis, this being caused by a sudden wrench, strain, or concussion; more generally the concussion will cause an extravasation of blood into the cancellous tissue lying just beneath the encrusting cartilage of the femur or tibia, or into the patella. This injury may appear but slight at the time, and cause the patient no great pain, and even if examined by a medical man may not be correctly diagnosticated. But if this apparently slight injury be not correctly diagnosticated, and the proper treatment be neglected, it will in time lead on to serious disintegration of the bone substance; a low grade of inflammation being set up, and pus formed, which slowly burrows into the joint, the encrusting cartilage becoming involved, leads on to necrosis; ulceration of the cartilage taking place because of its low grade of vitality, and soon the true bony structures come into contact, being denuded of their cartilage by the disease; there appearing at the same time a fungous exudation from the synovial membrane lining the joint, and which hence becomes rough and granular, the membrane being changed from its smooth, shining surface, and we have what is called gelatiniform degeneration of the joint.

This condition, which I have endeavored to explain to you, is simply the result of long-continued inflammatory action, and, as a rule, from some *slight* accident. If the injury caused acute inflammation at the time, it would have been noticed at once, and appropriate treatment applied. But in those slight injuries which pass unnoticed at the time, and months elapse before the real symptoms set in, this slight injury, occurring long before, is overlooked or forgotten, and the disease is pronounced then to be white swelling, there being no redness about the joint. And yet, for the reason that there is so much constitutional disturbance accompanying this swelling, the disease has been almost universally looked upon as of constitutional origin; whereas, in the great majority of cases, it is the result of a direct injury to the parts diseased; and the long-continued action, together with the slow inflammation, is what has produced this constitutional disturbance, and leads the physician into the belief that the disease is dependent upon some constitutional dyscrasia alone. There is no doubt that a constitutional dyscrasia *may* be inherited from the parents; you can also create a disease by bad hygiene, which, sooner or later, may bring about a strumous condition; and when you have reached this condition, no matter whether inherited or acquired, a very slight injury will start degenerative action very rapidly; much more rapidly than if the health of the patient were in a normal condition—as in the normal condition the system has more recuperative and resisting power than when diseased.

Now, I do not wish you to misunderstand me on this point; but I will distinctly state that in persons laboring under this strumous diathesis, whether inherited or acquired, some local effect is necessary to start the disease. In constitutional diseases, they are diseased all over; then why should the disease manifest itself at one particular point more than another? Simply because it is a traumatism that has produced this external manifestation of the disease at this point.

The tendency of this inflammatory action is to produce an effusion into the joint, which causes a certain and characteristic distortion of the joint. Thus, in disease of the knee-joint, we find the limb partially flexed at the knee, because by this flexion of the limb the capsular ligament becomes relaxed, and the joint-cavity can then contain more fluid, and thus relieve the diseased parts from pressure. The same explanation is equally applicable to disease of the hip-joint; the limb is flexed in order to distend the joint capsule and accommodate the increasing effusion. In the course of time the muscles themselves begin to contract, owing to reflex irritability, and these in turn draw the diseased

surfaces of the bone together, and thus diminish the amount of blood to the parts pressed upon, and therefore interferes with the nutrition of these parts, resulting in severe and extensive ulceration from this lack of vitality of the part. You can, then, readily understand how this pressure adds to the torture of the patient, besides inducing a more rapid disintegration of the parts pressed upon.

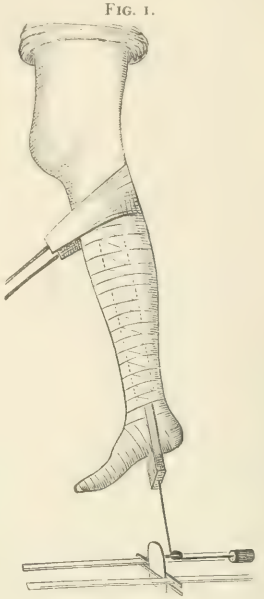
In the knee-joint, then, we have this flexion and outrotation of the leg, the biceps muscle constantly acting upon one point only, keeps up this continued pressure upon the outer condyle of the femur. For this reason the leg is rotated outward. On the inner side of the leg we have the insertion of the sartorious, semi-tendinosus, semi-membranosus, and gracilis muscles, which act against the biceps alone on the external surface of the leg; these four muscles having different points of insertion, do not maintain their traction at one particular point; there is no continued pressure upon the articular surfaces at one point at all times; thus the inflammatory action is more tardy at the internal aspect of the joint; whereas the biceps, acting upon one point alone, allows of no relief from pressure, and thus does more damage than the other four muscles combined. This is the reason of the peculiar deformity accompanying disease of the knee-joint.

If, in connection with this diseased condition of the joint, you have constitutional disturbance—torpor of the bowels, or affection of the kidneys, etc.—it is necessary to give this condition the requisite treatment; but do not pin your faith to any so-called specifics, for there is no remedy on the face of the earth which will take the place of fresh air and good nourishing diet in this class of cases. The local treatment, however, is of the most vital importance, and if you omit that, your patient will never recover with a good and useful joint. The general treatment, independent of the local treatment, is not sufficient. You must, therefore, apply some means to overcome that distortion, by the use of traction in the required direction to correct that deformity and relieve that pressure. In these diseases of the knee-joint, you will find your patient sitting, holding his leg, until he becomes worn out by the constant effort of keeping it in one position, in order to prevent attrition of the diseased surfaces. In your treatment of this disease, if you simply lock the knee up, you will make a failure; you must have *extension* with it, or the contracted condition of the muscles will add to the progress of the disease. In contradiction of the statement I have just made, I will quote from the twentieth annual report of the New York Society for the Relief of the Ruptured and Crippled. "Weights and pulleys to extend diseased limbs are never used in this hospital, as we believe them to be mere palliatives in treatment, and often injurious."

There is no need for me to make any lengthy comment on such a statement, and the results arising from this plan of treatment in diseased joints, as the large number of cases which have been presented at our clinics for treatment, after being under treatment for months at the above hospital, have fully proved the fallacy of such a statement in relation to the proper method of treatment of diseases of the joints.

In disease of the knee-joint where the leg has become flexed, you will first require extension made in two directions, one upward and the other parallel with the long axis of the limb (see Fig. 1). If I attempt to straighten a limb in this position by parallel extension only, I simply add to the pain; but by securing the limb with extension in the *two* directions, namely, in

FIG. 1.



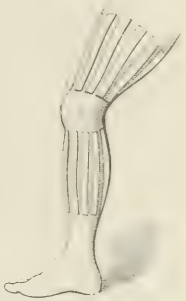
the line of the deformity, I afford instant relief. If you can place the parts in such a position as to afford relief, that is all there is for you to do; but you must carry out that plan. Sometimes it may be necessary to apply heat or cold. You may think that somewhat strange, but it is a fact; neither can I tell you which to apply, or when to apply it; you have to judge by the feelings of the patient, and apply that which affords most relief. In one case you may apply ice with great effect; if this, however, causes pain, relief may be derived from heat in all probability. Now, if there is but very little swelling in the joint, but intense pain over the coronary ligaments, then you can apply the hot iron over these ligaments and allow the wound to cicatrize; but under no circumstances get up a suppurating sore. You may, perhaps, need to apply a blister, and when the blister is raised, just let out the exudate, but do not take off the skin or you will be liable to have a suppurating sore also. After letting out the fluid, you cover the part with a piece of oiled rag. This is the only proper way to apply blisters; the actual cautery, however, you will find most efficient in these cases.

After you have, by means of your traction, brought the leg almost straight, you can then apply the knee-splint, which I here show you (see Fig. 2). In preparing the limb for the application of this instrument, cleanse it thoroughly in order to remove all particles of exudate which would prevent the adhesion of the plaster, which I now intend to show you how to apply. In the appli-

cation of any kind of splint in which adhesive plaster is used, I prefer to use Maws's or Shivers's moleskin plaster, which I here show you, and which can be procured from Messrs. Hunt & Dunlap, 1218 Broadway. In

FIG. 2.

FIG. 3.



applying this knee-extension splint, I cut inch-strips of plaster, as you now see, which are long enough to pass from just above the knee to the upper third of the thigh, and allow sufficient to reverse over the collar of the splint. I now pass more strips from just below the knee to a little above the ankle, and in like manner allow of reversing over the bottom collar of the instrument. We now have the plasters adjusted, leaving the knee exposed (see Fig. 3).[1] My assistant now holding the limb and plasters in position, I take a roller-bandage and bind very firmly around the limb, and then, with my hand, by rubbing, I firmly secure the plaster to the skin; and now, as I remove this tight bandage, you see they remain in their place without my assistant holding them, and he is at liberty to assist me in other ways.

I now take a roller-bandage, and place permanently around the leg, to retain the plasters in position; then I secure those upon the thigh in the same manner, still leaving the knee exposed, you will oberve. I am now ready to apply the splint. First, I secure the lower collar—by means of the key I regulate the size as may be required, to prevent strangulation of the circulation; then, reversing the ends of the adhesive plaster over the collar of the instrument, you notice I secure them in that position by passing a strip of adhesive plaster around the leg directly over the collar of the instrument. Having thus secured them, I now continue with my roller-bandage over the collar of the instrument and under the extension-rods around the leg, and over the reversed ends of the adhesive plaster. In this manner we have secured the lower part of the splint, and will now turn our attention to the upper part of the same. I desire specially to call your attention to this collar, inasmuch as it allows of motion upon the rods of the splint; whereas, in the lower collar of the instrument, you noticed that it was perfectly immovable and could not possibly be moved upon the rods, as in this upper collar. If, now, both of these collars were movable, you could not retain the leg in any one position, for the simple reason that the collars would tilt upon themselves, and thus, while the upper edge of the lower collar and the lower edge of the upper collar would press in upon the leg and cause excoriations, your extension would be lost and the joint surfaces brought together, and the disease within the joint, instead of diminishing, would increase. I mention this the more especially as it is but a few weeks ago that a child was brought to my office wearing an extension knee-splint, in which both collars were movable, and which was made by Tiemann & Co. The physician who brought the child to me came from Canada; he told me that he wrote for my splint, and received such a one in return. Now, I wish to be distinctly understood upon this point, and cannot impress upon you too strongly the necessity of one collar being firmly fixed and immovable upon the extension-rods, for it is only those that I use; the other, in which the two collars are movable, is perfectly useless, and is not my splint. The same thing has occurred to me in the splint made by Shepard & Dudley. The splint which I here show you is made for me by Reynders & Co., 303 Fourth avenue.

Having now secured both upper and lower collars in a similar manner, still leaving the knee exposed (see Fig. 4), I now take my key and make the requisite extension, which will be when my patient tells me he is free from pain. You will notice that, while doing this, my hand is under the upper third of the leg, pressing upwards. This is to prevent the anterior surfaces of the joint from being brought together while I am making extension. Having now secured the requisite extension, and the patient being free from all pain, we shall endeavor to secure the absorption of the effusion around the joint, and for this purpose I now take some strips of adhesive plaster about an inch wide, and bind them firmly around the joint, leaving no place uncovered; by this means I secure an equal pressure all over the joint surface. Having accomplished this, I now pass a roller-bandage around the joint over the plaster, and thus retain them in position (see Fig. 5). Anyone

FIG. 4.

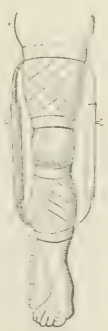


FIG. 5.

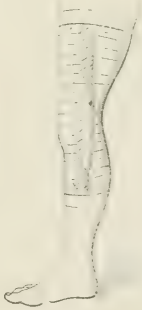

FIG. 6.

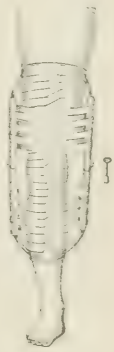

looking at that leg now, would perhaps suppose that was the end of the dressing; and I regret to say that I have seen some students who manifested so little interest in

[1] The strips of plaster on both thigh and leg should be longer than they are represented in this cut.

the pursuit of their studies, and although, perhaps, wishing to see the instrument applied, would rush from the lecture-room because it was almost the close of the hour, and think they had seen enough to warrant them to apply the instrument if they should ever be called upon to do so; whereas, by this very thoughtlessness and carelessness, they lost one of the most important points in the application of this knee-extension splint; and perhaps by this very carelessness, when an opportunity offered, would ruin both their own reputation and the leg of the patient. I therefore desire you specially to observe this last and final application of the bandage, and make careful notes of the manner in which I apply it. You will notice that, having now bandaged the knee, I carry my roller up the thigh, passing it over the thigh in front and under the rods of the instrument, bringing it in front of the thigh only—not behind at all. By this means I press the femur back and assist in straightening the limb. Having done this, I now pass my roller down below the knee, but instead of passing it in front of the leg, as I did with the thigh, I pass it behind the leg and over the front of the rods of the splint, thus forming a cradle for the leg and still further straightening the limb. This last bandage, you will notice, takes the place of my hand, which I just now drew your attention to, as pushing the tibia forward to prevent any pressure upon the anterior surface of the joint (see Fig. 6).

You have now seen the complete application of the extension splint in disease of the knee-joint. But, supposing that your patient is very heavy, I should advise the use of a pair of crutches in addition, as the weight of the patient may cause the adhesive plaster to slip, and thus necessitate constant reapplication of the splint. If, however, it is a child, there will in all probability be no need for the use of the crutches, and it can run about with the splint as you have just seen it applied.

Case I.—This boy, whom I now present to you, was brought to me some time since suffering from disease of the knee-joint. He was then nine years of age, and out of a family of nine children the only one who is in any way failing in health. He was strong and healthy until he was four years old, when, I am informed by his mother, he was supposed to have had some trouble with his kidneys, and shortly after he was attacked with otitis of both ears, ending in perforation of the drum, with more or less discharge up to the present time. You have all observed that, in addressing him, he is compelled to use an ear-trumpet.

Some four years ago a swelling was observed upon the inside of the right knee after exercising. He was taken to a distinguished surgeon of Philadelphia, who, the mother stated, advised massage and gentle motion. Failing to get relief under the treatment, and the swelling still increasing, another eminent surgeon was then consulted, he giving his opinion that it was white swelling, and advised a course of constitutional treatment with the external application of iodine, no mechanical treatment at that time being advised. The leg becoming flexed, the attending surgeon afterwards ordered an instrument for the purpose of bringing the leg straight; but the *main feature* required was lacking in the instrument, there being *no extension* made with the endeavor to straighten the limb. No relief being obtained by the constitutional treatment, or the mechanical appliance, after two years of this method of treatment, and the disease still increasing, the attending surgeon then advised amputation of the limb. Before consenting to this, however, the father decided to bring the boy to me. At the time that I saw him the knee had lost all its contour; there was a large abscess over the joint, fluctuation extending two-thirds up the thigh. On the inside of the inner condyle was a sinus, into which a probe could be passed through the joint, emerging at the upper portion of the tibia. The leg was flexed at an angle of forty-five degrees, and the least motion caused intense pain. The measurement being taken over the patella, gave eleven inches against eight and a half inches around the sound limb; below the patella, the diseased limb measured ten and one-eighth inches against eight inches below the patella of the sound limb, the muscles of the calf of the diseased limb being greatly reduced in size, owing to disuse. Upon making traction upon the leg in the line of the deformity, *e. g.*, in the two directions, as is my usual custom in disease of the knee-joint when the limb has become greatly flexed (see Fig. 1), immediate relief was obtained. I therefore determined to delay amputation until he had had the advantage of my plan of treatment, and at once ordered him to be placed in bed and extension made in the two directions, previously making a free opening into the joint, passing a rubber drainage-tube through the knee from the inner condyle to the outer portion of the tibia, and another one from above the knee and aspirating the abscess at the thigh; these operations being performed antiseptically, the joint being tightly strapped and the limb carefully bandaged. The extension was maintained for six weeks, until the limb had been brought sufficiently straight, so that the extension knee-splint could be applied in the manner already described. This has been reapplied from time to time, as occasion has required, and extension made within the limits of prudence, until, as you see, the leg has been brought almost straight.

He comes to me now able to walk upon the leg without pain or discomfort, the sinuses having since closed. The result is much better than I could dare anticipate; but I am in hopes of securing still better results, as I shall presently show you.

I refused to operate when he was brought to me, as he was in such a miserable condition that there seemed very little hope for his life if amputation were performed. I thought then it would be an excellent recovery if he could be cured with ankylosis. I now find the patella quite firmly attached, but by using a little force I can secure slight movement, although it causes considerable pain. Now, by bearing down upon the leg, I can bring the limb almost to a straight line, and having secured such a condition of things, I feel inclined to do more than to let him go with the limb in its present position. I certainly see no reason why it should not terminate in a movable joint.

You see that I move the tibia on the femur easily enough, but the patella does not move at all. If I can succeed in loosening the patella, I am quite certain that something can be done by developing the quadriceps muscle. This is a lesson of practical value, and I hope you will see the importance of the continuance of further treatment; although, in this case now before you, we have a most satisfactory and remarkable recovery. I

have ordered an instrument to be made by which the leg will be thrown forward. The principle is to carry your treatment up to the point of endurance, but not to a point of exciting fresh inflammatory action. Remember, that if by your passive movements and massage you create heat and pain in the joint, and they have not disappeared on the following day, then you have carried it to excess, and should, therefore, give the joint perfect rest, with the application of cold water, until all inflammatory action has passed away.

Now, I desire you to understand the importance of motion and massage at the proper time. During the active progress of the disease, *rest, rest, rest,* is the essential element of the treatment, and at the same time extension sufficient to prevent pressure of the diseased surfaces against each other, induced by reflex muscular contraction. But when the inflammation has subsided, and all morbid action has disappeared, then passive motion may be instituted for the purpose of preventing ankylosis.

If you understand the principles of this, you will have no difficulty in these cases of ankylosis; and remember that you have no right to stop until you have secured all that is attainable.

Note (nine months after).—There is now excellent motion in the joint, the patient being able voluntarily to extend the leg to almost a straight line; and can flex the knee to a right angle. He can now run around with ease, and this winter has skated with his companions.

Case II.—This man, aged forty-two years, comes here from Nebraska suffering from what is sometimes called hydrarthrosis. You will notice how immensely this left knee-joint is swollen. Upon taking the measurements we find its circumference to be: Above the patella, twenty inches; at the upper edge of the patella, twenty-one and one-half inches; at the lower edge of the patella, eighteen and one-quarter inches. The measurements of the knee of the sound leg are: Above the patella, thirteen and three-quarters inches; at the upper edge of the patella, thirteen and one-half inches; at the lower edge of the patella, thirteen inches. You observe that he can flex the leg perfectly and extend it almost to a straight position, and can also walk upon it. He states that he has been to the Hot Springs, and to one of the hospitals in St. Louis, and has had numberless applications to the knee, but to no avail. He had the knee aspirated twice in St. Louis, a quart of fluid being removed on each occasion, he states; this, however, I think is doubtful.

He tells me that previous to this difficulty, while carrying a pail out with feed for his hogs, he slipped and fell, striking the side of the knee violently, since which time the knee has gradually assumed its present proportions. The difficulty in this case is that while able to walk upon the limb, he can never be sure of it supporting him, as without a moment's warning it gives way and throws him to the ground.

On examination I find that the external condyle has been fractured off, and as you here see, I can take the whole piece in my fingers and slide it up and down as I wish; while if I take hold of the internal condyle and attempt to make motion, I move the whole thigh. We have, therefore, an ununited fracture of the external condyle with this enormous swelling of the joint. Now what can we do here? The only way is to have some artificial support for the limb, to prevent the man from having these sudden falls. This support must be designed to keep the leg in position, so that when the weight of the body is brought upon the leg it cannot be thrown off its point of bearing. Mechanical means is the only treatment which can be of advantage in these cases.

NOTE ON THE USE OF HYDROBROMIC ACID IN EPILEPSY.

BY HORATIO C. WOOD, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND CLINICAL PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE UNIVERSITY OF PENNSYLVANIA.

THE researches of Dr. Reichert in the physiological laboratory long since showed that hydrobromic acid is so nearly equivalent to the bromide of potassium, that it ought to be able to replace the salt to a considerable extent in practical medicine, as being more agreeable to the taste, and not having any potash in it to increase unnecessarily the depression of the circulation and disturb the general nutrition.

Nevertheless, the verdict of those neurologists who have used hydrobromic acid has been strongly against it, and my own earlier experience coincided with this. Thinking over the matter, it occurred to me, that this negative result had been caused by the failure to use the remedy in sufficient amount. One or two teaspoonfuls of a three per cent. solution (Fothergill's formula) seems to have been a common dose.

The acidum hydrobromicum dilutum of the United States Pharmacopœia is a ten per cent. solution, yet one drachm of it is only equivalent in bromine strength to nine grains of the potash salt. A teaspoonful of Fothergill's solution represents scarcely three grains of the bromide. It is plain, therefore, that much larger doses of the acid should be employed.

In my ward at the Philadelphia Hospital there are twelve cases of old, severe, essential epilepsy, which from August 13, 1883, to September 15th, were taking each seventy-five grains daily of the bromide of sodium, and in most of which the acne and other evidences of bromism were very pronounced. During the thirty-three days these twelve patients had two hundred and twenty-seven fits. Of these fits one hundred and thirty-two occurred during three days in one patient, and probably should be deducted, for the purposes of comparison, leaving ninety-five as the number. The patients were then left fifteen days without medicine, were then given a half fluidounce of the officinal hydrobromic acid three times a day for twenty-three days; after this the dose was increased to six fluidrachms for six days; then to one ounce for forty-three days. After this, for sixty-two days, they were given each ninety grains of the bromide of potassium daily. The results are expressed in the following table.

The smaller number of fits in the first entry of the second column is obtained by deducting from

the whole number the many fits occurring during three days of epileptic status in one person.

Medicine. Daily Dose	Number Days.	Number of Fits.	Averages number of fits occurring in the 12 patients conjointly, per day.
Bromide of sodium, 75 grains.	33	227 (or 951)	6.9 (or 2.9
No medicine.	15	241	10.1
Acidum hydrobromicum dilutum, f℥iss.	23	81	3.5
Ibid. f℥ijf℥ij.	6	12	2.0
Ibid. f℥iij.	43	79	1.8
Bromide of potassium, 90 grains.	62	132	2.2

It will be seen that the effect of the acid in reducing the number of fits was directly proportionate to the dose, and was very pronounced. When three fluidounces were given daily, the number of fits was reduced to about one-tenth of those which occurred when no remedy was administered: whether the great number of fits which happened during three days of epileptic status is deducted or not from the roll of the sodium bromide, the effect of the acid was much greater than that of the seventy-five grains of the salt.

Even the largest dose of the acid was better borne than were the seventy-five grains of the bromide of sodium. The eruption of acne was much less universal, and when present much less severe, whilst the peculiar apathetic countenance of bromism was entirely wanting, although it had been very distinct in several of the cases whilst the salt was being administered. The effect of a daily dose of ninety grains of the bromide of potassium upon the recurrence of the convulsions was not as great as that of the full doses of the acid, but the bromism produced was distinctly more severe.

The acid was given after meals, with an equal amount of ginger syrup. Each dose was diluted with a full half pint of water, and no evidences of gastric irritation or other disagreeable symptoms were produced. It must, however, be borne in mind that the cases were old epileptics from the lower ranks of life, and in robust general health, with insensitive, powerful digestive organs, so that I think in private practice these large doses should for the present be used with caution. I have, however, given half ounce doses to a delicate girl without perceptible evil effects of any kind.

1925 CHESTNUT STREET, PHILADELPHIA,
December 14, 1885.

SOME POINTS IN THE DIAGNOSIS OF BRIGHT'S DISEASE.

BY ROBERT T. EDES, M.D.,
PROFESSOR OF MATERIA MEDICA IN HARVARD UNIVERSITY, BOSTON.

THE name of Bright's disease has been attached to so many and such varied cases, and has lately been so broadened by high authorities, that a little inquiry into the correctness of this very general application is by no means undesirable. An excellent way to clear up one's ideas on the subject is for the student, or, still better, the practitioner, after he has become well indoctrinated into the pathological anatomy and symptoms as taught in the text-books, and after having made sundry excursions into the more speculative regions of "high tension" and "lithiasis," to consult the works of Dr. Richard Bright, when he will realize how much travelling in a circle has been done since they were published, and might be tempted to remark that what Dr. Bright didn't know about Bright's disease isn't worth knowing. This would, however, unless looked at simply as expressing his just admiration for the completeness of the discovery of that eminent physician, be a decided exaggeration. One of the points which he did not know, and which have since been found out, is the extreme frequency with which some symptoms of the affections going under this name are met with, as consequent to or associated with other diseases, where they assume entirely a secondary rôle in importance. What he did not know, and what no one yet knows, is the nature of the connection, so well understood to exist, between the cardiac, vascular, nervous, and renal changes. At present the fact is so well known that many affections which would once have been characterized as independent diseases, such as apoplexy, dropsy, and cardiac disease, are very likely to depend upon, or to be associated with, a chronic nephritis which has before given no decided sign of its presence, that this condition is likely to be diagnosticated as an explanation of almost any sudden and serious set of symptoms, and the diagnosis may be sustained by the exhibition of what are supposed to be the pathognomonic features, viz., albumen and casts in the urine. Thus, a case of coma from opium-poisoning may present a very close resemblance, not only in the general condition, but in the state of the urine, to the sudden supervention of so-called uræmic symptoms.

The public is willing to accept Bright's disease as an explanation of almost anything obscure or unexpected. Any middle-aged or elderly man who has a pain in his back, a little difficulty in urinating, or, on the other hand, some incontinence of urine, or who notices in his chamber-pot on a cold morning a deposit, full, to him, of the direst forebodings, but known to the chemist as urates, can be made to believe that he has Bright's disease as easily as a broken-down anæmic woman, with a pain in her back, can be persuaded that she has "womb complaint."

The amount of truth in the two cases is enough to save the doctrine from contempt, and make it worth while to consider some of the mistakes in diagnosis somewhat seriously.

The desirability and importance of setting right the misapprehensions of a supposed sufferer are by no means small, from the amount of mental relief which is thus given, and the question loses none of its importance when considered in reference to the advertisement of "cures" and stories of wonderful recoveries.

It is not necessary, of course, to point out to physicians that neither pain in the back nor its absence, nor the irregularities in urination just mentioned, have any direct value in the diagnosis of Bright's disease, but there is reason to suppose that some other symptoms have attained a position of somewhat exaggerated importance in the minds even of the profession, and are considered more conclusive than experience shows them to be.

Albuminuria is now so well known to occur in a great variety of diseases, and even in some conditions not involving serious or permanent impairment of health, that it is to be looked on rather as a reason for further inquiry than as having by itself a very distinct meaning. Casts, especially of the hyaline variety, are not so generally known to belong very much in the same category. While the writer does not agree with Charcot in believing that casts may occur in a healthy urine, any more than that a purulent sputum comes from a healthy bronchus, it is undoubtedly true that they are often found under circumstances where nothing more than a temporary disturbance of the renal circulation, or some local irritation, exists as a cause. The kidney may be more or less affected, but it is not so primarily, and the renal trouble is not the essential one. Thus, it is not unusual to find a case of valvular disease of the heart, or even of general failing health, connected with fatty degeneration of the heart and consequent feeble circulation, suspected of being Bright's disease from the presence of albumen and casts in the urine. The renal atrophy of old age is not infrequently attended with casts.

If we turn to another symptom, which is of the highest importance in diagnosis, which should always be inquired for, and, if necessary, investigated by daily measurements, namely, polyuria, we find ourselves confronted with another set of difficulties. Of course, the practitioner will not allow himself to be led astray by the statement that the patient arises several times in the night to pass water. This is, to be sure, a suspicious circumstance; but it may arise from a local irritation, or even from simple nervousness. (In the latter case, by the way, the valerianate of zinc has been found a very effectual remedy.) A real polyuria may exist in surgical cases from irritation of the neck of the bladder, retention of urine, and back water in the kidneys, or from a renal calculus. This may be accompanied by albumen and a few transparent casts, and is dangerously near to the line which separates irritation from a chronic interstitial nephritis, which is not infrequently the final result. It is not, however, Bright's disease, and the distinction is a highly important one, since, if the local obstruction or cause of irritation can be removed by surgical measures, the renal atrophy is not necessarily progressive. This kind of polyuria is to be distinguished by the presence of the causative lesions, and especially by the presence of an excess of mucus, pus, and epithelial elements from the urinary passages.

A moderate polyuria of nervous origin, or, in other words, a mild diabetes insipidus, may, from the presence in small amount of the abnormal elements we have been considering, assume the appearance of chronic contracting kidney. The difficulties of diagnosis are by no means slight when we find ourselves in the presence of a case involving not only polyuria with albumen and casts, but nervous symptoms, such as are commonly found in this combination, as vomiting and headache. A cerebral tumor may present the greatest similarity of symptoms to a chronic nephritis, and we may have not only the phenomena just mentioned, but, in addition, others which are more or less common in the two diseases. These are optic neuritis (although this generally presents points of difference, as it may be associated either with intercranial pressure or with arterial degeneration and retinitis) and also high arterial tension. This latter condition, although often present in chronic nephritis of the interstitial form, is too frequently found in other affections to have the supreme importance recently attributed to it, either in reference to diagnosis, pathology, or treatment. The writer, several years ago, was demonstrating a sphygmograph to a little circle of medical friends, and just as the instrument was writing off a tracing which should have been highly characteristic of Bright's disease, or chronic interstitial nephritis, on the wrist of a gentleman about sixty years of age, another asked, "what is this high-tension pulse they are talking about now?" The question was evaded as well as possible, but the subsequent career of the patient, if so he could be called, as well as that of another member who gave a similar tracing, was watched with much interest. The first died about three years afterward, but as both the symptoms and the autopsy showed in the most conclusive way, of cirrhosis, not of the kidney, but of the liver. The second is still, at the age of seventy or thereabout, actively practising his profession.

The symptoms which are most characteristic in each of the affections mentioned above, which are to be specially sought in any case of doubt, are in cerebral tumors, *localized* headache, paralytic conditions of limited groups of muscles or spasm of corresponding groups, and the etiology, which is likely to be syphilitic. For the nephritis, we have the cardiac hypertrophy and the dropsy, usually slight. It is, however, but rarely that the two diseases will approach so closely that the analysis of the urine affords no assistance in making the distinction.

Migraine may be closely associated with polyuria, albumen, and casts, and then certainly makes about as perplexing a problem as can well be met with; one which it is probable can only be solved by time, and even then not so conclusively as to leave the physician and patient altogether free from unpleasant doubts.

It is, of course, open for any one to say that such a case is only in the early stage of a chronic form, and it would be almost impossible to disprove such an assertion. The writer has had under observation for some years a lady who has for a long time been subject to severe headaches, with vomiting. She has had constantly a small amount of albumen and a few casts in the urine, which is rather abundant and of low specific gravity. The sphygmograph

shows somewhat high tension. This looks like a pretty clear case of progressive interstitial nephritis, but although the headaches are perhaps more severe, in the intervals the patient is able to be out and about. At one time she greatly improved under a milk diet, and there has been no appearance of the more characteristic symptoms, such as cardiac hypertrophy or dropsy. Time alone in such a case can assure us that chronic interstitial nephritis will not become more manifest, and go on to the usual termination.

Some of these obscurities in diagnosis may help to explain many of the "cures" of Bright's disease. While the writer would not be understood to deny the possibility of an arrest of a chronic nephritis of either form, which may amount to a cure with a more or less damaged but still sufficient kidney, yet the ordinary professional and lay opinion as to the extreme rarity of such an occurrence, is undoubtedly correct; and few of the cases where a complete recovery from chronic Bright's disease is said to have taken place, will bear a close scrutiny. Where the diagnosis is that of the ignoramus, or of the interested quack, it is not worth while to spend time in accounting for remarkable cures. The explanation is very simple. As has already been said, it does not require a specially credulous patient to accept such a diagnosis, and the marvellous feats of therapeutics are very easy if the intending performer has the opportunity to make the diagnosis to suit himself, and retain it uncontradicted. In other cases, however, I believe that mistakes have arisen from, firstly, the very distinctly intermittent way in which many cases of Bright's disease pursue their course, or perhaps to the occurrence of exacerbations which disappear under the influence of rest, warmth, and appropriate treatment, and give place to decided improvement, which may be taken for recovery. I have seen a man with parenchymatous nephritis, marked cerebral symptoms, and great dropsy, leave the hospital well enough to make a voyage to sea before the mast, and return with the same symptoms, of which, although I have lost sight of him, I have no doubt he finally died. Again, an attack of acute nephritis does not always begin with pain in the back, fever, and exceedingly scanty urine, which at once signify its character; and if appearing, as it not very rarely does, simply as a rapidly increasing dropsy without marked pyrexia, cerebral phenomena, or in fact any of the classical symptoms to announce its true character, it is very likely to be taken for the development of a previously latent chronic disease. If this suspicion is taken as a certainty, and the patient then recovers, the case passes for one of a wonderful cure of Bright's disease, instead of what it really is, the usual and natural result of acute nephritis. Even in the nephritis of scarlet fever some of the signs, especially casts, may hold on so long as to deceive one into thinking of chronic rather than of acute disease.

In some one of these ways nearly every one of the reported cases of "cure" can be accounted for, without either doing great violence to our only too well-founded pathological ideas or impugning the good faith of lay narrators.

THE ETIOLOGY OF TYPHOID FEVER.[1]

BY EDWARD G. JANEWAY, M.D.,

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM AND OF CLINICAL MEDICINE IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE most important questions relating to the etiology of typhoid fever are, whether it is alone spread by direct or indirect contagion, or whether it is possible that the cause of the disease at times originates independently of a person sick with the disease. In other words, assuming that a bacillus is the cause of this disease, does such germ only come from some one suffering with an attack of typhoid fever, or does it exist more or less widely distributed in favorable localities, having no connection previously with typhoid fever, but occasion the disease when it has found an entrance to a proper subject? These questions have been the occasion of considerable dispute in the past, nor is such matter settled yet beyond controversy. There are many difficulties in the way of a satisfactory examination of the subject, and in not a few cases we are unable to reach a positive conclusion.

In rural districts and in institutions, typhoid fever seems not infrequently to spread by contagion, as person after person sickens with the disease. Yet in not a few of these instances it can be shown that such contagion is not direct, but indirect. In studying this question of contagion, we are obliged to examine the matter in two ways. We must first satisfy ourselves that the person sick with the disease contracted it at the supposed place; and, secondly, that there was no other rational explanation for such sickness than that of the emanations from the sick. To go more into detail, when a person who is in contact with a patient suffering from typhoid fever contracts the disease, the following possibilities are presented for solution—assuming that, because of continuous residence in the place, the only question is from what in that place was the disease obtained:

1st. The same cause which operated in the production of the first case may have been again efficient.

2d. The excreta from the sick may have produced contamination of the drinking-water, or may have found their way into cesspool, sewer, etc., and the active principle of the disease become reproduced, and, being received by the second person, caused the sickness.

3d. If we can satisfy ourselves that in neither of these ways, nor by any of the other avenues through which the typhoid fever germ gains admission to the system, was it probable or possible for the patient to have contracted the disease; then, and then only, are we forced to the conclusion that the contagion was direct. We must admit that there are many loopholes, and that very few cases would stand a rigorous examination and be capable of proving that typhoid fever was spread by direct contact. In not a few cases we will be obliged to say that it was possible, not certain. In those instances where I have examined into this matter I have not found one by which I have been forced to this as the

[1] A paper read before the New York County Medical Association, February 18, 1884.

absolute and only conclusion. The negative side of the question, too, must be examined in order to estimate the extent of this danger, if such exists. Error is very liable to occur if too much reliance be placed upon this method of procedure; nor is it safe to say that because ninety-nine have not taken the disease, though directly exposed, that the hundredth person did not. The usual method of studying this aspect of the case is to cite the instances of hospital nurses, attachés, and patients, waiting upon or in close proximity to typhoid fever patients by reason of occupying the same wards, and to show that these either did not or did in no considerable numbers sicken in consequence. Those who believe in contagion cite those who contracted it under these circumstances as instances of direct contagion; whereas, the opponents endeavor to offset this by supposing that such instances are to be explained upon the basis of imperfect sewerage of such hospital, etc. The frequency with which typhus fever is contracted under similar circumstances is used as a foil by those who are opposed to accepting the idea of direct contagion.

The writer has had considerable opportunity of watching the difference manifested by these diseases in this respect, especially with reference to hospital nurses. He is obliged, however, to admit that he has known instances of physicians, nurses, and patients contracting typhoid fever in an institution where typhoid fever was received. On one occasion a house physician sickened with the disease, but at the same time an employé of the hospital, who had no contact whatever with typhoid fever patients, but who was exposed to emanations from the same line of sewer which was imperfect in in its arrangements, and was in the physician's room, contracted the disease. During the past autumn three nurses who had been attending typhoid fever cases were under his care; two of these had typhoid fever, the third had probably aborted typhoid fever. But in each instance sanitary defects existed in the hospital or house where the disease was contracted.

Moreover, with reference to the nurses in hospital, four patients contracted the disease at the same time. Two of these occurred in wards in which no typhoid fever was received, and it was necessary to admit that direct contagion could not have been efficient in their cases. They, however, used water-closets in connection with sewers receiving typhoid fever excreta, and more or less imperfect. The nurses were exposed to these same sewer emanations, as well as to the direct emanations from the patient. The writer, moreover, had reason to believe that the disinfection of the passages from the bowels was imperfectly performed. In order to arrive at a just conclusion in this matter, an inquiry has been made at several other hospitals receiving typhoid fever patients. The result of this inquiry is in the main negative. All claim that no nurse or patient in the wards contracted the disease; but in one, some years ago, one of the physicians contracted typhoid fever while residing in the hospital, and in another a domestic sickened with the disease.

The hospitals interrogated have been the New York, Presbyterian, St. Luke's, Mount Sinai, Riverside, and Bellevue.

The result of this part of the investigation is that typhoid fever does, at times, occur amongst those resident in a hospital receiving patients with the disease, but that the number of cases where this has not taken place would point towards failure of disinfection or to defect in the plumbing of the institution. Such occurrence, too, is an illustration of another fact—the spread of the disease by the sewers independent of the ground water.

The principal source of typhoid fever in New York City is to be looked for in defective sanitary arrangements, permitting the entrance of the emanations of the sewers, either to the air or to the drinking water of which the patient makes use. In a large city, and particularly in the fall of the year, these sewers receive enough germs from typhoid fever cases to make any investigation as to whether the disease arises spontaneously, or always from germs which have been derived from the excreta of typhoid fever, impracticable. It would be a great mistake to suppose that invariably where sewer emanations gain entrance to a house, and even where the defects are very great, typhoid fever will appear. The writer has seen marked exceptions to such an idea; exceptions which, together with the susceptible character of those exposed, only prove that something more is necessary than ground saturated with water and sewage in order that typhoid fever should occur. Diphtheria has sometimes occurred under such exposure, and not typhoid fever. Again when apparently far less vitiation of the air has occurred, typhoid fever will break out. In other cases, the defects have existed for a long time, the so-called sewer gas has been vitiating the air, but no typhoid fever has appeared; when at length one or more of those exposed sicken with fever.

Such illustrations show that it is not as is so frequently supposed by the laity, or as is often laxly said, the sewer gas, but something added thereto, which has gained entrance to the system through these sanitary defects. Many suppose that the determination of the question as to the method by which the poison gains entrance to the system is easy, whether by the air or by the drinking-water. But the writer has found in a number of cases that the determination of this matter is not of such easy solution. If we suppose that germs are floating in the air the question must be again raised, Do they occasion the disease by being received through respiration and by the lungs, or are they by this act simply drawn into the mouth and throat, and thence swallowed with the saliva, food, and drink, to develop in the alimentary tract? The writer thinks that this latter is the method more probable.

Anyone who has examined much the sanitary defects in cases of typhoid fever, will find that vitiation of water is in many cases possible, especially at the present time, with our defective water supply and water pressure. The drawing of water on a lower floor causes a partial vacuum, which, if stop-cocks are open, or if tanks supplied by ball-floats, which open the pipe when the water is lowered, are more or less empty, or by defective valves to pipes

on water-closets with direct supply, causes an aspiration of air into the water-pipes of the house. How forcibly this suction is, anyone can estimate by allowing the water to run on a lower floor, and then opening a stopcock connected with the pipe on a higher story. The same danger exists through the overflow-pipe of tanks when they discharge into sewer-pipes. The writer has traced outbreaks of typhoid fever in two institutions to sanitary defects of this nature, and operating in this way. Occasionally much more radical defects are witnessed, and that at times in houses which have been pretty carefully examined. The writer has seen water-pipes connected with the sewer-pipe of a house. This is very ordinary for the discharge of the water from the boiler in the kitchens of our houses. It would be difficult to suppose that this could, under the circumstances of its position, and the relation of the pipe to the range, be a source of trouble. But the connection of a small pipe from the supply-pipe of a water-closet directly with the sewer-pipe of a house is a menace of a more serious nature.

There are cases on record of severe outbreaks of typhoid fever, due to the sucking of sewer-air and its accompaniments, or even of some of the liquid sewage, into the water-pipes of an institution or of part of a town. Such accidents happen when the water supply is intermittent, or has been for any cause withdrawn from a district and the pipes been emptied of water. In these cases, where small leaks are in proximity to defective sewers and drains, or by methods above indicated, either liquid sewage or air from such source may be drawn into the water-pipes. The experience of Liverpool, in its attempt to increase its water supply by cutting off waste and leaks, shows that there is more danger of this than many would suppose, who think that where there is a leak the outward pressure will always prevent harm. When we read that it was impossible for the steam fire-engines to obtain water at a recent fire, we see a source which is not alluded to of drawing by suction, through defects, dangerous matter into the water-pipes. Much, of course, of such harmful matter would, under the circumstances, be again discharged; but the fact of the ready emptying of the mains by powerful suction is ominous.

Attached to the tenement-houses of New York City, a large number of privy-vaults still exist. There is but one form of these places which is devoid of danger if properly cared for. The school sink or trough-closet does not admit, except by gross carelessness, of that accumulation of filth which is the abomination of those other places; moreover, it can be readily cleansed and disinfected in case of typhoid or other infectious disease appearing in the house. The question of origin in such cases, with or without the germs from a pre-existing case of fever, is in a large city as impossible of a just decision as in the case of defective sewerage.

The following illustration will exemplify this: A pedler, who was a patient with typhoid fever in Bellevue Hospital, stated that he had been affected with the diarrhœa of this disease for the week preceding his admission to the hospital, and that during that week he had plied his vocation in different portions of the city, using, as the occasion demanded, the conveniences of tenement-houses. He admitted that he had probably visited forty-eight such places during the week. The writer knows of no recorded instance on this matter which better shows the possibilities in this direction.

That such places serve to develop the poison of typhoid fever there is sufficient evidence, and the method of action may be in one of three directions: 1. By the use of the place. 2. By the leakage from such places causing saturation of the soil beneath a house. 3. By the connection of the living rooms of a house with such places by waste-pipes. The writer has seen cases which justified him in believing that in each of these ways typhoid fever was contracted. The attempt to remove these places and to cause the substitution for them of trough-closets, or a proper form of water-closet, has in the past been the cause of considerable difficulty between the owners of tenement-houses and the Board of Health; and the writer is obliged to add that the courts have at times taken the ground that such places are not nuisances *per se*, but only that in individual instances they may become nuisances.

For several years the Board of Health has refused to allow any to be constructed. But under the law the tenement-house owner has the option of a trough-closet or some form of water-closet. The writer has feared that, with the defective water supply and consequent deficient flushing of soil-pipes, an increase of typhoid fever might result from the introduction of water-closets in the tenement-houses on a large scale. In how far some of the increase of the disease may be attributed to this cause he has been unable to learn. Fortunately a portion of this danger has been avoided by the plumbing law, through whose instrumentality the Board of Health can locate the position, and regulate the construction of the plumbing. The Board cannot, however, prevent misuse, and cause constant cleanliness to be observed, but too often can only act when the evil has occurred. The moral responsibility rests with the owner of the property to prevent evil by the enforcement of thorough cleanliness through proper supervision, and also by providing an ample supply of water for flushing.

The spread of typhoid fever by the use of polluted water in the city of New York is not limited to the methods by which, as has been pointed out, the Croton becomes contaminated. In the upper portion of the city, and especially in the annexed district, wells, with all the attendant liability of sewage pollution, are still in use. So, also, there are a certain number of wells within the built-up portion of the city. The writer was able to trace the outbreak of typhoid fever in an institution to the use of such water by the employment of the chloride of lithium test. The place was supplied both with Croton water and had a pump on the premises, within fifteen feet of which ran a sewer from the hospital building some five hundred feet away. Mr. Nealis, the Inspector of the Board of Health, had been detailed to examine into the cause of a number of cases of typhoid fever in the institution. He

found the disease mostly limited to the boys, in whose playground the pump was, though the institution contained both boys and girls. The plumbing of the institution had been thoroughly overhauled. These facts led him to suspect the pump. We advised that the drain going from the hospital be exposed, suspecting that we should find a leak, but though thirty feet were laid bare in either direction, the ground did not show the least indication of leakage. Moreover, a chemical analysis of the water did not prove it to be especially bad. Under these circumstances the writer suggested the use of chloride of lithium as a test. An ounce dissolved in a pail of water was poured down the sink of the hospital. Water was taken from the well an hour before this, and each hour for six hours subsequently, and on the next day. Dr. Waller, of the School of Mines, made a spectroscopic examination of the water, which showed no lithium in the water before or on the day after the journey of the solution into the pipes, but that it was present during each hour at which water was taken on that day. This showed undoubted communication between the sewer and the well. The disuse of the water was followed by cessation of the fever. The pump-water was used by the boys as they played, and also because its taste was preferred on the table to Croton water. As each of the boys who was taken sick was removed to the hospital, it can be readily seen that this furnished a very good means of propagating the disease. The writer does not know who first suggested the lithium test, but he has not heard of any other instance of its employment.

In many cases the chemical analysis shows such evidence of sewage pollution, and the position of the well with reference to sources of contamination, cesspools, privies, etc., is so open to suspicion that it is very justly suspected of being the cause of an outbreak of the disease. But there is a caution necessary in that in each case all the possibilities should be carefully weighed, because, notwithstanding the use of polluted water, it may be that that has not been the direct exciting cause. Instances are common in which use has been made of such water for a considerable period without the development of typhoid fever. A single case of the disease in any locality does not afford the groundwork for fair reasoning. But when a number occur at the same time, or consecutively, then we have a basis upon which to rest. In an investigation which the writer made of the causes for an outbreak of the disease in a neighboring college, the method of procedure can be illustrated.

He had charts furnished him showing the name of each person sick, the date of sickness, the boarding-place, and the building in which his room was situated, and so far as possible what he drank. There had been some thirty cases of fever, which seemed to be distributed pretty generally in the different college dormitories. But an investigation started in this manner showed that though the first six to come down with the disease lodged in different buildings, yet they all took their meals at the same house. Moreover, in these dormitories at that time no other serious sickness occurred. Hence this house became justly suspected of originating the trouble. Later it was discovered that a servant employed in that house also sickened with fever at the same time.

Within this house was a water-closet discharging into a cesspool with earth sides and bottom, in a shale soil, forty feet distant from a well. The water of this well was found on chemical analysis to be seriously polluted. Another cesspool from the kitchen was also within a short distance. These six persons became ill, with one exception between March 15th and April 1st, all previous to April 1st.

The first to be taken sick not only had his meals, but roomed in the house with the suspected well. It was about the middle of May before other cases began to occur, with two exceptions. These, however, did not room in the college buildings. Four of the six thus taken sick in April had rooms in three of the college dormitories. The sewerage was by water-closet, discharging into two cesspools, in different directions. Some of the sick remained only a short time after coming down with the disease, but one stayed throughout the whole course of his illness. The excreta were thrown into the water-closet, and reached one of the cesspools. The overflow of this was obstructed by some of the neighbors, and was over quarter of a mile from the college. After the middle of May the disease became distributed to the different buildings connected with the cesspool. The water supplied to the college was tested frequently, but showed no chemical evidence of contamination. As a holiday had intervened, and, morever, as on the breaking out of the disease again it did not select the dormitory in which the sick student had remained, but affected particularly a dormitory which stood nearer to the cesspool; and, moreover, as radical defects were found in the arrangements which had been made for the ventilation of the sewer by a chimney in this building, it was rendered morally certain that the disease had spread, not by the drinking-water, not by the air, nor by direct contact, but by means of the emanations from the sewer and cesspool into which the passages from those sick with the fever had been thrown without disinfection. Moreover, the disease affected others in the town who had no intercourse with the sick, but only became affected through the vitiated sewer-air.

To show how negligent people are even after a warning, the writer may be pardoned for alluding to an occurrence in this same town over six weeks later. In the mean time the college authorities had done every possible thing to improve and remove the causes of the trouble. The writer had made a visit to the town with a view to ascertaining the amount of sickness still prevailing. He found that in two adjoining houses, using a pump in common, there was in the ground beneath the spout, a gutter which led into a drain supposed to be open, but which a short time before had been found closed. The people had been in the habit of throwing the slops from the house into this gutter, and it was proved that this must all have found its way into the well. Three of the people in these two houses had typhoid fever. Moreover, the writer heard of

an instance in which one of the students going home with the disease, several other cases had followed at his home. These were at first attributed to direct contagion, but they had emptied the slops and the wash-water in such a manner as to render pollution of the drinking-water a matter of great probability. Disinfectants had not been used, owing to the nature of the disease at the college not being known at that time. As regards the question of origin of this outbreak, whether spontaneous or from a previous case, the writer was unable to come to a positive conclusion. It is true that the first person sick had come from his home a little over two weeks before he became ill, but he had gone home in poor health several weeks before this. The cause of ill health was said to have been malaria. An inquiry by Dr. E. M. Hunt failed to prove that he brought the disease from home or that anyone else had been sick at that house or visited there after convalescing from a sickness.

The writer could enumerate other instances in which an institution in the country became affected, without any proof being obtainable that a first person had brought the disease.

Other avenues by which the disease may be introduced in a house, and of which the writer has seen possible, though not positive, illustrations, are by means of refrigerators having direct sewer connections, and containing milk and food. In such case the former would be the more probable vehicle.

The writer has been able to connect only one outbreak in this city with affected milk, possibly diluted with water coming from a contaminated well, etc., as in the cases reported from abroad, especially from England. One of these occurred this fall in a portion of London, and seems to have been pretty clearly traced to this source. The number affected was over four hundred. In the case above cited it seemed extremely probable that milk had been the vehicle, as the gentleman whom he saw in consultation only drank milk and Clysmic water and other probable sources had been excluded.

With relation to the intimate nature of the agent which produces the disease, the writer, without any such careful examination for himself, is prepared to admit that it is, in all probability, a bacillus, and that it is possible that the one which has been figured and described by Eberth is the correct one. All this chain of reasoning would seem to point to such an agent as a logical necessity.

The writer has reached the following conclusions with reference to the etiology:

1st. It is in all probability due to a bacillus.

2d. That this virus is certainly contained in the discharges from the bowels.

3d. That it gains entrance to the system through the air coming from places into which the discharges of other typhoid fever patients have been deposited; or through water contaminated by a similar process; or through milk diluted with contaminated water, or perhaps vitiated by contaminated air.

4th. That there are instances which point to the probability that the germs which produce typhoid fever may develop in a suitable soil, but not have been derived from a preëxisting case of the disease.

5th. That it is not necessary to invoke the aid of the rise and fall of the ground water to explain the disease; though a low state of the ground water, by favoring an increase of the impurities in a well or water supply, may favor the spread of the disease, as may also a sudden severe rain after a draught by washing impurities, including the germs of the disease, into the drinking-water.

6th. That the failure of the disease to spread when prompt and thorough disinfection of the excreta has been performed, as well as of clothing soiled by such discharges, makes it extremely doubtful whether the disease is communicated by the respiration, perspiration, etc.

7th. The writer has had no opportunity to study outbreaks of fever resembling typhoid, such as have occasionally been met abroad, and ascribed to the eating of diseased meat.

One feature in the study of the etiology of typhoid fever is of considerable importance, and is deserving of special consideration, in order that we may have more certain information in the future from a frank recognition of what is obviously a growing evil. The writer has frequently felt, in dealing with statistics on this subject, some uncertainty with reference to accepting the facts from the mortality statistics at their face value. Some years since the Board of Health endeavored to find out from physicians about the prevalence of the malarial group, and the Sanitary Superintendent, Dr. Day, addressed circulars and maps to a number of the more prominent practitioners, and those having the most extended practice, asking their coöperation; but the attempt came to naught through the lack of interest displayed and the failure of response on the part of the profession. So also in the majority of instances any inquiry by letter or otherwise with reference to a death certificate has been looked upon as a sort of insult, and by arousing an immediate antagonism has prevented any fair result being achieved. I may be allowed, having no longer any connection with the Board of Health, to ask of the profession a correction of these matters in the future.

The tables which the writer had made in connection with the study of this subject, give in detail the number of deaths which have been ascribed to each of a number of febrile diseases since 1852. A noticeable feature observed, is the change of nomenclature which has taken place. Until 1862, a certain number died simply of fever. So also the terms bilious, hectic, gastric, miliary, and nervous fevers were in use.

Of these, at the present time, only the term gastric is occasionally used. But then and now intermittent and remittent fevers are assigned as causes of a considerable number of deaths. The term typho-malarial came into vogue in 1871, as the cause of twelve deaths, and since that time has been employed with increasing frequency. So also continued fever, without specification, and congestive chills have been the terms employed to account for the fatal termination of disease in eighteen cases during the year 1883.

The result is that a large total is reached in each year by the malarial class of diseases, and in each of the last four years more deaths are ascribed to these diseases than to typhoid fever. Four hundred and sixty-nine in 1880, six hundred and five in 1881, four hundred and forty in 1882, and five hundred and twenty-five in 1883. In these numbers one hundred and thirty to one hundred and fifty-four deaths in each year from the hybrid typho-malarial fever are included. As far as New York City is concerned, the writer regrets the employment of this term. It has led to confusion, and has furnished a happy avenue of escape in doubtful cases; which, like many other easy roads and short cuts, lead into a quagmire of doubt and misconception. Moreover, it has prevented those proper measures from being employed which would prevent the spread of typhoid fever, and lead to an investigation of its causes. The writer has long insisted that the evidence of post-mortem examinations is opposed to the use of the term, and he has known cases which clinically seemed, and were asserted to be, typical of this combination, which only presented the ordinary anatomical conditions of typhoid fever. The writer does not mean to deny that in very malarious sections of country some cases of typhoid fever would show certain appearances of a by-gone or complicating malarial poisoning; but to assert that, so far as New York City is concerned, it must be extremely rare. In fact, cases considered typho-malarial are as far as the great majority are concerned typhoid; in a few instances they may be remittent; the rest are illustrations of mistaken diagnoses, tuberculosis, masked pneumonia, etc., being the condition present. Moreover, when we find it stated that four hundred and seventy-one deaths occurred from typhoid fever, and five hundred and twenty-five from intermittent, remittent, typho-malarial, and continued fever and congestive chills in 1883, this is in direct opposition to the teaching of post-mortem examinations. According to this, we should see forty-seven cases of typhoid to fifty-two of these other complaints.

The writer, from a long experience in hospital practice, can assert that true intermittent and remittent fevers proving fatal are not indigenous; they occur mostly in people coming from subtropical or tropical climates. For a long period he has given his attention to the place of origin of well-developed intermittent fever, and he has been surprised to see how large a proportion has occurred in non-residents, or those having a temporary residence out of the city and in a malarious region. As of typho-malarial, so of the rest of the class; some of these others are typhoid, others tuberculosis, internal suppuration, pneumonia, etc. But this uncertainty is of importance because it prevents the acquisition of true information about the increase of typhoid fever. Manifestly, it would be incorrect to class all or perhaps even half of these cases as typhoid. These cases, too, have a direct bearing upon the etiology of typhoid fever in that, by failure of the disinfection of the evacuations, and also of the places in which they are deposited, they serve to allow of the increase of the disease. In Bellevue Hospital six hundred and fifty-three cases of malarial fever have been treated during the past three years with only three deaths. The writer has not had time to make an inquiry of other hospitals upon this point, but there are those here who can answer it.

Year.	Typhus.	Typhoid.	Remittent.	Intermittent.	Bilious.	Chagres.	Congestive.	Gastric.	Nervous.	Total of diseases other than typhoid and typhus.

1883	15	471	154	172	174	9	12	525

The relationship of age to the development of typhoid fever is of considerable interest. I have been unable to obtain the ages of the reported cases for this city, as such table has not yet been prepared. But in considering the tables of mortality for the last ten years, it will be observed that more than half the mortality occurred between the ages of ten and thirty. So also it will be noted that the disease is uncommon as a cause of death during the first year of life, only sixteen cases having been reported during the past ten years in a total mortality of over thirty-one hundred from typhoid fever during this period. Neither is it a frequent cause of death during the first four years of life, one hundred and seventy-five cases having been reported for this period. It will also be observed that the mortality gradually decreases for the ages over thirty, and

more particularly over fifty. Still three deaths are recorded from this cause between eighty and eighty-five, out of the totals above given; seven between seventy-five and eighty years, sixteen between seventy and seventy-five, and a total of two hundred and thirty-four above fifty years of age. The tables will give the number at the different quinquennial periods.

We can more readily understand the exemption of old age than that of infancy. There are, however, it seems to the writer, several reasons which are of importance in helping to solve the reason for this state of affairs. The diet of infancy is largely of milk and of mother's milk. Hence there is freedom in a great measure from one of the chief causes of the disease. There have been several outbreaks of the disease attributable to milk, but were there a very great danger from this source, then we should expect to have the tables reversed. Some may imagine that the characteristic changes in the bowels are not recognizable in infancy. There exist sufficient examples to disprove this idea. In fact, cases are cited which would go to prove the possibility that the disease began in fœtal life or just after birth, so as to force the conclusion that the mother might receive the germs of the disease and transmit them to the offspring without herself suffering from it. A greater probability is that some of the cases classed as entero-colitis, are due to typhoid fever poison.

A greater reason for the less frequent existence of typhoid fever in the earlier periods of life, relates, in the writer's opinion, to the fact that these infants are, in many instances, not alone less exposed to the danger from water, but also from contaminated air. When we reflect for a moment upon the methods employed for excremental removal in childhood, we shall see that they are in considerable measure removed from the danger of breathing cesspool or vault air.

A fourth suggestion is that, where danger from milk exists, this is in a considerable measure neutralized by boiling for preservation. The main intensity of the disease falls upon the last summer and early autumn months, during which many people are forced to resort to this expedient in cities.

A fifth hint is that mistakes are made in diagnosis, both as between typhoid and other diseases, and as between other diseases and typhoid fever.

As regards old age we have the increasing resistance of the system to the poison of certain other diseases, as well as of typhoid.

Deaths in ten years according to age:

Under 1 year,	16
" 3 "	175
5 "	203
5 to 10 "	243
10 to 15 "	416
15 to 20 "	554
20 to 25 "	371
25 to 30 "	319
30 to 35 "	204
35 to 40 "	159
40 to 45 "	138
45 to 50 "	112
50 to 55 "	68
55 to 60 years	55
60 to 65 "	49
65 to 70 "	36
70 to 75 "	16
75 to 80 "	7
80 to 85 "	3

The disease has prevailed here particularly during August, September, October, and November. The accompanying tables of reported cases and of deaths will show the facts in the case. The number of cases reported is not equal to the amount of the disease, nor can the proportion existing be accepted as a proof of liability to fatality, owing to the undoubted failure of certain physicians to report their cases.

A question of some importance arises whether the disease is increasing; as before stated, an uncertainty exists owing to the number of possible cases included under other heads. But I have had the mortality tables so arranged, that the fatality from typhoid, typhus, and the other fevers likely to be confounded, can be studied side by side. Since 1879, the writer knows that typhus means typhus, and for the four years before that the cases given as such in the mortality sheets, were only accepted on inquiry from the physician reporting such. The study of some of the previous years makes it possible that errors crept in, as when typhus was prevailing typhoid increased. It is a singular fact that many foreign cities still include the deaths from typhus and typhoid under one head. This renders a study of comparative prevalence of the disease difficult.

MEDICAL PROGRESS.

LIGATION OF THE EXTERNAL ILIAC ARTERY.—On December 11, 1883, DR. GAETANO DESOGUS performed the operation of ligation of the external iliac on account of a wound of the femoral artery. The patient recovered.—*Gaz. degli Ospitali*, January 16, 1884.

OSSIFICATION OF THE BRACHIALIS ANTICUS.—Many cases of ossification of the deltoid or of the adductor magnus have been observed among soldiers, and have come to be looked upon somewhat as professional lesions. RASMUSSEN now reports two cases of ossification of the brachialis anticus occurring at the military hospital at Copenhagen. After prolonged muscular effort, a tumor appeared in the middle of the muscular mass of the arm. It was very hard and painful, and easily distinguished from the biceps in front and the triceps behind. There was considerable functional trouble, and movements caused pain. Complete extension of the forearm could not be effected. The acute stage having passed off under the use of cataplasms, a sling and rest, the tumor was found to be reduced, but resembling an osseous growth from the humerus, and involving the brachialis anticus. After treatment, which did not exceed one month, the patients returned to duty. In one case the osteophyte diminished markedly in a month. Rasmussen is inclined to believe that the affection is caused by rupture of muscular fibres and of the fibres of the insertion of the periosteum; this is followed by an extravasation of blood, which is progressively transformed by a simultaneous regression and osteogenesis. —*Archives Méd. et Pharm. Mil.*, January 16, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 23, 1884.

LEGISLATION REGULATING THE PRACTICE OF MEDICINE IN NEW YORK.

THE necessity of placing certain restrictions around the practice of medicine, in the interest of the community, has impressed itself upon the legislatures of many States, and has led to the enactment of various laws on the subject. The question as to the propriety of such legislative enactment governing the practice of medicine, naturally divides itself into two parts. First, is legislative interference desirable or necessary for the proper protection of the community, or in the interest of the profession, or both? Second, granting an affirmative answer to the first question, how far should such interference extend?

Anyone who is familiar with the state of the practice of medicine in England as it was forty years ago and as it is to-day, or as it is now in those of our own States in which efficient legislative regulation exists, as compared with that in which no such laws are in force, must admit that good results may follow such enactments. Exactly how much advantage has accrued to the community it is difficult to determine; but it is reasonably certain that money has been saved to its members, and permanent loss of health, and probably even of life, averted. That the profession must gain by the elimination of a class of unscrupulous and ignorant pretenders from those allowed to prescribe and dispense medicines is too evident to require demonstration.

It being clear that we may reasonably expect good to accrue to the community and to the profession by appropriate State legislation, in what should this consist, and how far should it go? In the first place, has the State any right to lay down the law to its citizens as to whom they should consult in any given illness, or forbid their taking any treatment which their own choice or that of their friends may select? Clearly not, so long as their own health, and not that of their neighbors, is jeapordized thereby. Prof. Huxley has justly said, in a recent address on this subject, "it would surely be a monstrous thing that a man having the toothache should not go into the first druggist's shop and ask the man behind the counter to give him something that would do him good." And we say, with him, "do as you please; go to anybody you like" for advice.

On the other hand, the State clearly has a right to insist that those whose certificates as to causes of death, or condition of health, it receives, or those to whom it trusts its immediate employés, or those upon whose opinions it depends for counsel, should have certain qualifications; that they should not be pretenders, or knaves, or blockheads. Not only this, but it owes to its citizens protection against such, by placing them out of their reach as far as possible—by depriving them of legal recognition. This is practically what is done in England, although we believe it is not commonly so considered. As we understand it, anyone who chooses can practise medicine in England, but he cannot, unless he possesses certain qualifications, be registered; and therefore cannot collect his fees, or give testimony at a coroner's inquest or in a court of law; nor are his certificates as to causes of death recognized. A man who is shorn of these prerogatives has not much to practise for.

The question next arises, How shall the proper qualifications be secured? It is evident that no laws would be necessary if medical colleges were what they should be; but as they are not, and are not likely to be for some time, some other measure must be taken to secure the end so much desired.

At the first blush, it would seem that the simplest and most efficient method would be for each State to appoint a Board of Examiners, independent of the medical schools, who should test the candidate for registration in the branches, a knowledge of which constitutes a thorough medical education. To say nothing of the difficulty of securing examiners with the requisite qualifications, two others are to be overcome before this idea can be carried out. The first is that of securing a Board independent of politics, the influence of which, always baneful, is especially destructive to the honest exercise of the offices of a body in which special educational qualifications should alone be the criterion of appointment.

The second difficulty may be more apparent than real; but it strikes us as being an essential one in

the way of the attainment of the highest objects of legislation. In the existing state of public opinion, it would, of course, be impossible to enact a law which does not acknowledge, in some way, the so-called systems of medicine, including, at least, homœopathy and eclecticism. To our mind, it is utterly incompatible for the adherents of these different systems to sit in the same Board, and for those of one system to vote upon the qualifications of the adherents to another, with the practice of which they not only are not familiar, but also the principles of which they believe to be false. It appears to us that the only consistent plan would be to have a separate Board for each system, which would result in a complication of machinery, most troublesome, if not impossible, to manage.

But let us briefly examine how the question has been practically dealt with. The laws which have been adopted by some of our States go further than we have suggested; others, not so far. The former not only refuse to register such as do not meet the legal requirements, but they do not allow them to practise under any conditions. Such are the regulations in Illinois and West Virginia. Yet these States recognize the diplomas of a large number of medical colleges, and do not go behind them. Others, as North Carolina, Alabama, and Mississippi, require all candidates for registration—those holding diplomas and those not—to appear before State or county boards.

We have before us copies of the most recent Acts proposed for the settlement of this vexed question. They are those presented by Drs. Sturgis and Wey, at the late meeting of the New York State Medical Society. Both Acts provide for a commission of nine men, practitioners unconnected with medical colleges, to be appointed by the Governor and to be called the Medical Faculty of the University of the State of New York. The Sturgis bill provides for "representation of the several systems of medical practice recognized by the incorporated medical societies in the State, in the proportion of six, two, and one." The Wey bill does not provide for such representation. According to the Sturgis bill, *all* persons desiring to practise medicine after the passage of the Act, shall be examined by said board in anatomy, physiology, histology, pathology, theory and practice of medicine, chemistry, surgery, obstetrics, materia medica and therapeutics, and such other branches as said faculty may agree upon, subject to the approval of the Regents of the University. But all candidates for the examination must give proof that they have received a diploma from some legally incorporated college.

In the Wey bill, graduates of New York medical schools are exempt from this examination, but the Act provides for the presence at the examinations by the college faculties of three members of the State Board or Medical Faculty of the University of the State of New York, who practically supervise these examinations. The expenses to and fro and twenty-five dollars a day to each of the members of the Board are to be paid by the medical school whose examination is supervised. The Wey bill does not specify the subjects on which the candidates are to be examined, but the questions are to be determined by the so-called medical faculty, subject to the supervision of the Regents of the University. The Medical Faculty by both Acts can revoke, for cause, the license conferred.

Both bills provide for the payment of considerable fees by the candidates; the Sturgis bill fifteen dollars on application and ten dollars on issue of license, the Wey bill twenty-five dollars on application and fifteen dollars on issue of license. By the Sturgis Act, the Medical Faculty may even revoke, for cause, the charter of any medical college within the State.

The Sturgis Act appears to present the advantages of being more simple, more easily administered, and more just.

We do not understand why, as provided for in the Wey bill, the graduates of the schools of New York State should be exempt from examination, when it is well known that some of them are quite indifferent as to their conditions of graduation as compared with some in other States? It is true the Wey Act provides for a supervision of the examinations by these schools, but such supervision implies an interference with the internal arrangements of colleges which is likely to be resented and to lead to misunderstandings. It is better that the State Board should be in every way independent of the colleges. As it is through the medical schools, after all, that the qualifications of the candidates are to be secured, and as it is evident that the granting of degrees under proper conditions fosters a higher education, it is but right that every candidate for the State license should possess a diploma from a legally chartered institution, which is not essential in the Wey bill.

We believe that some provision looking to the preliminary education of the candidate before beginning the study of medicine, such as is required by the British Medical Council, which is now the registering body of Great Britain, would tend to accomplish more satisfactory results than a supervision of the college examinations.

It will be noted that the organization of the so-called medical faculty calls for nine members in each bill; the Sturgis bill dividing them among three systems, by which we presume are meant legitimate medicine, homœopathy, and eclecticism. The Wey bill calls for the same number, but does not specify the composition of the faculty. As this

is a question which must be met sooner or later, it may as well be met at the outset, and we think it an objection to the Sturgis bill that it does not specify more precisely what is meant by its systems.

The title adopted by both Acts for the examining boards—"The Medical Faculty of the University of the State of New York"—seems objectionable. The term "medical faculty" has so long been applied to a teaching body, that we think it must give rise to confusion. The Medical Council of the State of New York, or the Examining Board of the State of New York, would be more explicit. The practice in some of the States of characterizing these boards as State Boards of Health, or of making such regulations a part of the duty of Boards of Health, we deem of doubtful propriety.

The disciples of the New Code are already experiencing the difficulty of keeping their recently sought friends within control. The New York State Homœopathic Society, instead of immediately disbanding and falling into the proffered embrace of the other State Society, as was confidently predicted it would when the New Code was adopted, has the ingratitude not only to maintain its name and organization for all they are worth, but also, at its annual meeting, held at Albany last week, it has adopted a memorial expressing its disapproval of the medical bills presented at the late meeting of the New York State Medical Society, and now before the Legislature, and demanding that any board of examiners which may be authorized by legal enactment shall be composed of "three allopaths, three homœopaths, and three eclectics."

Having received the unsolicited indorsement of the New York State Medical Society, it is not unnatural that its substantial fruits should now be demanded by these irregulars; and if the New York State Medical Society is not ready, in the bills now pending, to concede to all "legally qualified practitioners of medicine" the equal standing which their State laws give them, then what does their New Code mean?

EVACUATION OF SPINAL ABSCESSES.

Prior to the introduction of antiseptic surgery, the treatment of abscess dependent upon caries and necrosis of the vertebræ was most unsatisfactory. A case was, however, now and then recorded in which recovery followed incision and drainage of the sac, this method having replaced subcutaneous opening by a valvular incision, which the accumulated experience of years had proved to be worthless. At the present day, the recognized procedure with the majority of surgeons is to open the abscess under antiseptic precautions, wash out the cavity with a germicidal agent, and provide for efficient drainage; but this operation is delayed until the abscess has steadily increased in size, or has approached the surface in one of the usual situations.

In a clinical lecture, published in *The Lancet*, December 29, 1883, Dr. Chevasse, of Birmingham, urges, first, that the cavity of the abscess be freely opened and adequate drainage established as soon as the diagnosis is complete, or before the pus has pointed; and, secondly, that the incision be made above the crest of the ilium, with a view to furnish easy drainage at the most dependent part as the patient lies on his back. Other advantages derived from opening a psoas abscess in this locality are, that the drainage-tubes may be omitted at an early date, that the drain-hole being very near the diseased bone, the three or four inches of abscess cavity below this point become obliterated in a few days, and that the antiseptic dressings can be applied and retained in position more readily than if the opening is in the thigh. Even in old cases in which the abscess has steadily progressed and burrowed beyond the thigh, Dr. Chevasse recommends the lumbar incision in the first instance, and a subsequent opening where the pus is pointing.

The next best position to open a psoas abscess is above Poupart's ligament, by an incision similar to that made in ligating the external iliac artery. The transversalis fascia having been reached, the abscess is rendered prominent by pressure made from below, or, should this fail, a probe carried through a small opening made in the thigh where the abscess is pointing upwards under Poupart's ligament, will indicate the spot for a free incision. After the tubes have been inserted the orifice in the thigh closes. The opening in this locality, not being so dependent, affords a far less direct route for the free escape of the pus than the lumbar incision, and the tubes must be retained for a longer time.

That the views expressed by Dr. Chevasse represent the practice of the more advanced surgeons of Great Britain, is shown by the debate which followed the reading of a paper on this subject by Mr. Treves, at a recent meeting of the Royal Medical and Chirurgical Society, which may be found in the *British Medical Journal*, January 12, 1884. With the exception of Mr. R. W. Parker, who preferred opening the abscess above Poupart's ligament, the speakers were in favor of the lumbar incision as affording the shortest and most convenient route for efficient drainage. Besides the advantages already referred to, an opening in the loin admits of ready examination of the diseased vertebræ, and the removal of a loose sequestrum, if present, as happened in one of Mr. Treves's cases, or of carious bone with the gouge, as in an instance recorded by Boeckel, in 1882, in his brochure enti-

tled *Fragments de Chirurgie Antiseptique*. The latter operation is, however, rarely practicable, but it may be resorted to when the disease is circumscribed and superficial.

In addition to the lumbar incision, the speakers, including Treves, Bryant, Macnamara, and Marsh, generally favored an early operation to prevent the formation of a large collection of pus. Mr. Noble Smith alone opposed this view, since he trusted to complete mechanical fixation of the spine, through which he had seen good results. If no improvement ensued, he opened the abscess.

The antiseptic lumbar incision of spinal abscesses, which Dr. Chevasse attributes to Mr. Chiene, but which, if we do not mistake, was first done by König, is certainly based upon correct principles, and we doubt not that the future will prove its great service. To what extent the incision through the structures of the loin will add to the dangers, experience can alone answer. If, however, we base our deductions upon the antiseptic opening of pointing abscesses, the risks should not be great, as we find that of 28 cases of this nature recorded by LACHARRIÈRE in his *Thèse pour le Doctorat*, 1883, only 5 were fatal, and that 2 of these were scarcely attributable to the procedure.

INCOMPATIBILITY OF SULPHATE OF QUININE AND IODIDE OF POTASSIUM.

IN a communication to the Biological Society, M. RABUTEAU calls attention to the ill effects of iodide of potassium and sulphate of quinine, when administered together or at short intervals. These effects are, on the part of the digestive organs, anorexia, nausea, epigastric pain, colic, and sometimes vomiting; on the part of the general system, *malaise*, slowing and feebleness of the pulse, pallor, and a sense of fatigue. These results are due to the decomposition of the iodide and the liberation of free iodine. This decomposition takes place, not alone in the stomach, but goes on in the intestine also.

The same result occurs from the use of an iodide sophisticated with an iodate of potassium. Iodine is set free, and to the action of this is to be referred the local and systemic effects above mentioned.

ANAL FISTULE IN TUBERCULAR SUBJECTS.

IN a communication made to the Société de Chirurgie de Paris, and published in the *Compte Rendu Général*, January 2, 1884, M. JEANNEL gives the details of two cases of operation for anal fistule in consumptives, one being in an advanced stage, and the second in the early stage of the disease. In both the wound refused to heal, but the general condition of the patients was improved.

From a therapeutic standpoint, these cases would seem to be successes, and to dispel the widely spread fears which are entertained by the laity, as well as by the profession, in regard to surgical intervention in the class of subjects under consideration. That conflicting views are held as to the propriety of interference, is a fact well known to our readers. While some surgeons maintain that not only the local but the general condition is ameliorated, others of equal experience and reputation condemn the operation, basing their opinion upon its inherent dangers and upon the ill-effects produced upon the lungs by the suppression of a sort of natural issue. In point of fact, in some cases, the operation may prove to be both a surgical and a therapeutical success, that is to say, the wound may close, and the pulmonary symptoms improve. In other cases, the fistule refuses to cicatrize, and the pulmonary lesions may either undergo no change whatever, or be aggravated. Hence, the entire question resolves itself into one of indications. If the local suffering be slight, an operation should not be thought of; but if the local distress be considerable, it should be resorted to, even if there be little prospect of healing of the wound.

THE ANTI-VIVISECTION AGITATION.

IN the February 9th issue of the *Philadelphia Medical Times* is an editorial in favor of the American Anti-vivisection Society, which is there spoken of as devoted to the "restriction of vivisection," so-called, "within proper limits," and not its abolition. If this be so, the name of the Society is sadly wanting in definiteness. What are the proper limits, is, we presume, to be defined, of course, by a collection of sensitive ladies, some clergymen, and two or three doctors with exceptional ideas. What the most active and enthusiastic of them state in private, is that abolition is their ultimate purpose, and the fairness of their methods may be judged of by the public citation of Magendie's experiments made when anæsthetics were unknown, as arguments against the present use of animals, and as illustrations of the abuse of vivisection.

In England the restriction bill has resulted in practical abolition, and incessant efforts to pass a total abolition bill. The profession knows well what it would mean to yield to this absurdity. Suppose that we granted the present demand, where would be our future security? Could we expect a fate other than that which has fallen upon the profession in England? Years ago we offered to accept such a bill as has since been passed in Great Britain. Happily hysterical counsels prevailed, and the ladies concerned promptly refused any aid which did not concede total abolition. In England there was no real cause of complaint as to misuse of animals, but to-day, with restriction, physiologists

have to go to the continent to complete their researches, or, as is often the case, do their work in private and in defiance of a foolish law unfairly worked. Are we prepared for such a state of things?

We were invited by one of the physicians who spoke at the anti-vivisection meeting, which proved so dismal a failure as to numbers and as to any interest the speeches caused, to meet these good people in a just and generous spirit of accommodative sweetness of temper. But the very existence of such a society is a calumny. In the past, many of its members have waged a bitter war of gossiping slander on physicians of the highest class, and have not hesitated even, of late, to propagate the most absurd stories concerning institutions of medicine. For any truly valuable purpose—for any evil in relative proportion to the machinery set in motion to crush it—this society has as little reason to live as if it were organized for the suppression of cruelty to vegetables.

The hyperæsthesia of sensitiveness may come in a true sense to be perilously near to cruelty, and there is a form of conscience so morbid, as Wendell Holmes says, that it requires another conscience to prevent it from doing evil.

REVIEWS.

A Handbook of Hygiene and Sanitary Science. By George Wilson, M.A., M.D., F.R.S.E., Fellow of the Sanitary Institute of Great Britain, etc. With Plates. Fifth edition, enlarged and carefully revised. 12mo. pp. 512. Philadelphia: P. Blakiston, Son & Co., 1884.

We are pleased to notice the appearance of the fifth edition of this work, which has been enlarged and carefully revised by the author. Dr. Wilson's handbook has been before the public for a number of years, and has been very favorably received not only in England, but in this country; the best evidence of this fact being the repeated demand for a new edition. The work occupies an intermediate place between such rudimentary books as the *Health Primers*, and the more elaborate treatises of the class to which Parkes's *Hygiene* and Buck's *Hygiene* belong. It is alike useful to the general public, the physician, and to those engaged in the administration of sanitary affairs.

A rapid perusal of the pages gives evidence of careful revision and an effort to bring the work up to date. In other respects this edition is a great improvement over its predecessors. The introductory chapter has been completely remodelled, the treatment of subjects more strictly belonging to the domain of social science having been omitted, and in its place has been introduced an historical sketch of sanitary science from the earliest ages to the present time.

A serious omission in former editions has been supplied by an addition to the chapter on Dwellings of a section on the sanitary inspection of dwellings.

The valuable reports of Dr. Thorne have been made use of to enrich the section on hospitals for cases of infectious diseases. There has been a demand for information upon this subject, due to a growing tendency in sanitary administration towards the adoption of the wise plan of isolating cases of infectious diseases in separate pavilions, and the suggestions here presented will prove highly serviceable.

Due prominence has been given to the subject of vital statistics, which has been enlarged upon and treated in a separate chapter. In handling the question, all abstruseness has been avoided, the object being to furnish a practical guide to those engaged in the ordinary work of compiling statistics of births, marriages, and deaths.

The last eighty-two pages of the volume are devoted to a detailed statement of the duties of medical officers of health, and to an Appendix containing official memoranda and data for the guidance of sanitary officers. Whilst referring specially to practices adopted by the Local Government Board of England, it will not be uninteresting to those engaged in similar work on this side of the Atlantic.

The volume is printed in large, clear type, and on good paper, and has the advantage of a full index and an ample table of contents. It is decidedly English in character, but this does not detract from its great excellence.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 22, 1884.

The President, R. F. Weir, M.D., in the Chair.

TRIPLE AMPUTATION OF THE LEG.

Dr. A. G. Gerster presented a man, forty-eight years of age, on whom three amputations had been performed. At the last one the patella, and both condyles of the femur, together with a portion of the old cicatrix, which was attached firmly to the posterior surface of the condyles, were removed. About a year ago the man suffered from compound fracture of the ankle-joint, which was not treated antiseptically. A phlegmon developed, and it became necessary to amputate the leg. Both of the flaps, however, sloughed. Although the amputation was treated by the open method, Dr. Gerster attributed the sloughing to the bad condition of the patient's circulation, due to habitual alcoholism. As there was no covering for the protruding extremities of the bones, and it was expected that the cicatrix would become ulcerated, amputation was performed a second time at the knee-joint by another surgeon. Most of the long anterior flap after this operation also sloughed, and the result was a large cicatrix upon the posterior aspect of the limb, closely adherent to the bone, and the final amputation already mentioned was performed. Dr. Gerster presented the patient especially on account of one pathological observation. When he had laid bare the condyles by the circular incision, he found that, instead of close union of the integument having taken place with the articular surface, a bursa mucosa existed between it and the cartilage. The amputation having been ac-

complished, Neuber's deep sutures were employed, one drainage-tube was placed in the cavity from which the patella had been removed, and only one sublimate-sawdust dressing was necessary. Four weeks after the amputation the man was able to walk on the stump, and was discharged from the hospital. The wound at the amputation was quite extensive and irregular, and he introduced about eleven sutures to bring about contact of the walls of the cavity with the patella. The lining of the bursa quadricipis was also removed.

DOUBLE BOWLEGS; MCEWEN'S OSTEOTOMY.

DR. GERSTER also presented a boy, sixteen years old, showing the result of double osteotomy, according to McEwen's method, for bowlegs. Nine weeks had elapsed since the operation, and the case progressed without any complications. The operative wounds were treated with a small pad of iodoform gauze. The distance between the internal condyles was three and a half inches before the operation, and now they touched each other. There was considerable arterial hemorrhage on one side, and he was obliged to ligate the bleeding vessel *in situ*. The limbs were placed upon simple straight splints, and allowed to remain four weeks, when the splints were removed, a silicate of soda dressing applied, and the patient allowed to walk about on crutches.

DR. LANGE said that he saw the last patient before his admission to the hospital, and so far as he remembered it was a case of genu varum, and the principal deflection was as it is now. In the course of the tibia, he thought it would have been better if an osteotomy had been done below the tuberosity of the tibia.

DR. GERSTER said that some of the deformity was due to curvature of the thighs, and his purpose was to determine whether or not it was necessary to osteotomize both femur and tibia; but finding that the osteotomy of the femur corrected the deformity, he proceeded no further. Doubtless, there was a marked curvature of the tibia also, but he considered the result as a very fair one.

DR. POORE asked if the femoral curve was the most marked of the two.

DR. GERSTER replied that the tibial curve was the most marked.

DR. POORE remarked that in genu varum the deformity is due chiefly to the tibial curve, and he supposed quite probably one difficulty in correcting it in this case was the loose condition of the ligaments, and on this account it is very difficult to correct the curvature.

DR. GERSTER remarked that he had had no difficulty in correcting the deformity after the bones were snapped.

DR. LANGE remarked that there now existed a slight degree of knock-knee, and the curvature of the tibia remained.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, February 7, 1884.

THE PRESIDENT, R. A. CLEEMANN, M.D., IN THE CHAIR.

A YEAR'S WORK IN OVARIOTOMY.

DR. WM. GOODELL read a report of his cases of ovariotomy during the past year. (See THE MEDICAL NEWS for February 16, page 178.)

DR. A. H. SMITH felt that Dr. Goodell was hardly right in saying that in England desperate cases are rejected. In his own experience, while in England recently, several cases which were very desperate, and which would have been generally rejected here, were operated upon successfully, and were ready for discharge three weeks after operation. It occurred to him that the lower average temperature had much to do with the result. The thermometer is not allowed to rise above 65° F. in the room in which the patient is kept, and in Lawson Tait's cases it rarely goes over 60°, and never up to 65°. Perhaps this has a good effect in preventing hyperpyrexia. The English ovariotomists are also very careful in details, especially in preventing hemorrhage, and use an immense number of hemostatic forceps. Ovarian cysts are remarkably common in London.

DR. B. F. DAWSON, of New York, upon invitation by the President, spoke of the English ovariotomists, and alluded to what he had himself seen while on visits to England as to very desperate cases being operated upon. His own late experience had been so good that he was inclined to attribute it, as well as the good results of the English operators, to absolute painstaking in the most trifling details, with absolute cleanliness; not simply antisepsis, but the utmost care throughout every step of the operation. Among other things, a very large number of hemostatic forceps are used to secure each bleeding point the moment that bleeding commences. His own last six cases of laparotomy, performed this winter, two of which were very desperate in their character, have been successful, and the results, he felt, were largely due to the avoidance of any preventable hemorrhage and great care throughout all stages of the operation to prevent blood or fluid from the cyst escaping into the peritoneal cavity. This care is exercised throughout the "toilet of the peritoneum," and he always uses a flat sponge, as does Mr. Wells, inside of the abdominal walls, upon the intestines while introducing the closing suture, which is removed only when it becomes necessary to do so to twist the last wires,

He always uses napkins to fold over the edges of the abdominal incision to prevent the oozing from the edges escaping into the peritoneal cavity, or soiling the operator's fingers. He also enfolds the cyst in towels as it is withdrawn from the cavity, to guard against even a trace of fluid soiling the intestines or wound. He clamps the pedicle temporarily when possible, and places a napkin under the clamp before dividing and cauterizing it. Every adhesion that shows any risk of bleeding, is cauterized as soon as it is separated, even when ligated. Douglas's pouch especially is sponged out until the sponges come away absolutely clean. In a recent very desperate case, one in which Dr. Emmett expressed his sympathy with him as to its almost certain fatality, the operation occupied two hours and forty minutes; owing to painstaking observance of the above details, and although half of the uterus was removed and adhesions were numerous, calling for many ligatures and frequent use of the cautery, yet convalescence was uncomplicated and speedy.

DR. GOODELL remarked that the quotation in his paper, to which exception had been taken, referred to Mr. Tait. It was taken from a paper read last autumn before the American Gynecological Society by Dr. Sutton, who was with Mr. Tait three months. He (Dr.

Goodell) had seen about a dozen ovariotomies in Great Britain, and only one was a difficult case, and in that the patient died. There he had seen patients refused on account of their age, while in this country they are not. He had operated successfully in patients aged respectively sixty, sixty-one, sixty-two, sixty-four, sixty-five, and sixty-seven years, and some one in this city had a successful case in a patient over eighty-three. He had once operated upon a patient seventy-six years of age, of a long-lived family. This was before the days of antisepsis, and the patient died. He believes that minute attention to details is the chief element of success.

One important point is to make the abdominal incision sufficiently large to see every adhesion as it is separated, and to ligate or secure immediately every bleeding point. This requires a courage which it took him years to attain. He always observes Spencer Wells's method of placing a flat sponge beneath the abdominal walls when introducing the closing sutures. He does not like wire, but always uses carbolated silk sutures, each eighteen inches long. After all have been placed, the ends are twisted together into one strand on either side and caught in the bite of a pressure forceps. The lips of the incision are then widely separated, and a final search is made for any oozing, leakage, or accumulation of serum. The sutures are then rapidly tied, and the wound dressed. This final toilet of the peritoneum cannot be made when wires are used. He now believes in the use of a drainage-tube, but he had hard work to bring himself to the point of accepting it, as he still looks upon the tube as a foreign body—a necessary evil. He had once seen death caused in a healthy man by the simple perforation of the peritoneum, without wound of the intestine, by a small stiletto, and this had made him fearful of the effect of the presence of a drainage-tube. But he now considered that the peritoneum in the case of an ovarian cyst has by thickening and attrition lost much of its vulnerability, and does not resent slight causes of irritation. He occasionally resorts to the actual cautery at a black heat to stop bleeding from torn adhesions, but he prefers the pressure forceps, the ligature, or the application of Monsel's solution.

He thinks there may be some truth in Dr. Smith's idea concerning the effect of the low temperature of the operating and of the convalescent room. He was struck with the absence of ill results in one operation in London, by Dr. Bantock, of which he had been a spectator. The day was cold, damp, and foggy, and the operating room was chilly, the windows being open; but the patient promptly recovered. One case of his own, in which the extreme emaciation and prostration of the patient forbade postponement, was operated upon in severe winter weather; the steam-pipes at the hospital had been frozen over night, and although they had been thawed out, the temperature of the operating room was only 54°. In this case the cyst had contained colloid matter, and had burst spontaneously; all that could possibly be removed, was scooped, sponged, and washed out. Much remained behind, yet the patient recovered and afterward became quite fat. This operation was performed three years ago, both ovaries were removed, but another tumor can now be discerned in the abdomen. The patient being fat and also quite sensitive, it is not possible to determine accurately its character, but he hopes it is a pedunculated fibroid of the uterus, and not a malignant tumor.

DR. DAWSON requested Dr. Goodell to give his opinion respecting the management of the drainage-tube, and of the importance of the spray.

DR. GOODELL said that, when operating in private houses, he has begun to dispense with the spray. Carbolic acid spray poisons some patients, and he, being afraid of it, only uses it when he does not consider it safe to omit it, as, for instance, in a general hospital, or where there are many spectators present. Year before last, he lost one patient from its use; she had contracted kidneys. Only last week in a case operated on in the Hospital of the University, the patient was profoundly affected by it and was with difficulty restored by means of digitalis, stimulants, etc. Where he omits the spray, he uses the drainage-tube more frequently. If he finds in Douglas's pouch, after the sutures have been placed and the sponges removed, two or three drachms of bloody serum, and the source of this oozing cannot be found, he inserts a drainage-tube; and he also uses it in all cases in which there has been peritonitis, or in which septic symptoms are present from a purulent cyst. Over the mouth of the tube he springs a piece of rubber sheeting, which is folded over a sponge squeezed out of a five per cent. solution of carbolic acid. The sponge is examined and squeezed out every few hours, and the tube moved slightly to clear the openings and allow any accumulation of serum to escape. As soon as a moderate amount of serum escapes without any tinge of blood, the tube is removed. This generally happens within forty-eight hours, but in one case it was necessary to allow it to remain five days. He never irrigates the abdominal cavity, but he sometimes introduces the long nozzle of a hard rubber syringe into the tube and draws out any serum that may have accumulated. When he operates in the country and leaves the patient in the hands of the family physician, he tries to avoid the use of the drainage-tube as much as possible.

DR. DAWSON had given some attention to the question of the drainage-tube. In New York two deaths had lately happened after ovariotomies, and in each case the surgeon had ascribed the fatal termination to the too early removal of the tube. Soon after these unfortunate cases he had operated, and had been obliged to use the drainage-tube; in the second and third days after the operation, the serum exuding from the tube was bloody. On the fourth day it was pure serum. The patient was doing well, and Dr. Dawson concluded to leave well enough alone, and, with the result in the two other cases before him, allowed the tube to remain. He used a wire with a pledget of absorbent cotton attached to the extremity, to soak out the accumulated serum, and continued to use fresh pieces until they came away clean. The tube was evidently being walled in by a deposit of lymph around it. On the sixth day, after finding very little serum, the last pledget of cotton brought away a little yellow spot that might have been either lymph or pus. That night he discovered another trace of the same appearance, and the microscope showed it to be pus. The next day the discharge was fetid. A saltspoonful of iodoform was put into the tube every time it was cleaned, and on the tenth day it was removed and a roll of absorbent cotton saturated with

iodoform was put in its place. This was replaced in a few hours with another until all signs of pus ceased. The opening closed in forty-eight hours. The patient recovered. He would like to ask if Dr. Goodell had ever regretted removing a drainage-tube too early? Is a drainage-tube more of a foreign body on the third or fourth day than it is on the first?

DR. W. H. PARISH had recently performed abdominal section for the removal of a fibroma of the uterus. In this case he used a drainage-tube, although he was not able to pass it down into Douglas's pouch. On the third day, he noticed that the serum escaping from the tube was cloudy and had a slight odor. On the fourth day, the odor was quite objectionable, and as the tube had evidently become separated from the abdominal cavity by the formation of a canal of lymph around it, resembling in appearance diphtheritic membrane, he decided to withdraw the tube. He washed out the canal with a two per cent. solution of carbolic acid. The canal soon closed and there was no return of the offensive odor.

DR. GOODELL could not recall the loss of a case after the removal of a drainage-tube. He has had, however, a number of deaths while the tube was still in position, but that meant simply that the cases were complicated and difficult ones. Was not the tube itself the cause of the pus in Dr. Dawson's case? Air containing germs was, of course, admitted into the tube in the cleaning-out process, and these germs would cause decomposition of the lymph. Might not also the tube, acting as an irritating foreign body, cause pus? He introduces a stitch in such a manner, beyond the drainage-tube, as to make tension of the skin around the tube, and this closes the opening as soon as the tube is withdrawn. He has occasionally followed the removal of the glass tube by the introduction of a rubber one of smaller calibre, but he has discontinued this practice believing the glass tube to be the least irritating.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 18, 1884.

THE PRESIDENT, WILLIAM DETMOLD, M.D., IN THE CHAIR.

A paper was read by DR. E. G. JANEWAY on

THE ETIOLOGY OF TYPHOID FEVER.

(See page 212.)

At the conclusion of the paper, Dr. Janeway said that he had intended, had time permitted, to make some inquiries in regard to the danger of contracting typhoid fever from water more or less contaminated with sewage; he had intended to institute more inquiries, similar to those which had been made on the Thames, concerning the relative prevalence of the disease in the cities of Troy and Albany. The sewers of Troy all emptied into the Hudson, and Albany, which was situated six miles lower down, derived its water-supply from the river after this sewage had been poured into it. In England it seemed to have been demonstrated that water which was contaminated with sewage, even to the amount of one to twenty, became innocuous after flowing twelve miles. The explanation generally accepted was that during this passage the organic matter became oxidized; but if it was assumed that typhoid had a special bacillus, the failure of the water to convey the contagium of this disease would probably be explained that the bacilli have all been absorbed or destroyed by other organisms in the transit.

DR. AUSTIN FLINT, SR., thought that all must agree that the subject of the paper was one of great importance, as well as interest, and that it was most judicious to bring it before the Association at this time. At the present time it was universally admitted that preventive was of greater importance than therapeutic treatment, and typhoid fever was beyond doubt a preventable disease. Our ability to prevent it would, of course, depend upon our knowledge of its etiology. He had listened with great interest to the paper, and he agreed in the main with the writer in his conclusions.

There were certain points in regard to typhoid fever which were of great practical interest. In the first place, it apparently depended on a special cause, a cause which was capable of producing this particular disease and no other, just as the various eruptive fevers depended each on a special cause. Whether the disease was due to a specific germ or not, had not as yet been proved, but reasoning from analogy, it seemed altogether probable that it did depend on a microscopic organism, and in due time he did not doubt that it would be demonstrated beyond question. In the second place, was this special cause always derived from the body of a patient suffering from the disease, or could it spontaneously arise under certain conditions? He did not think that he was prepared to say positively that the first proposition was true; but, reasoning again from analogy, we could infer that the germ, which, for convenience, at all events, it might be called, always did originate from the body of a typhoid fever patient. It was by no means always possible to trace the origin of the disease in any given case, but neither was this always possible in diseases which were recognized by all as contagious, such as smallpox and scarlet fever.

In the third place, this special cause had been shown to be capable of preserving its activity for a very considerable period—at least two years. Again, it seemed to be well established that the germ was introduced into the system in two ways: first, through drinking-water, or other liquids diluted with water; and, second, by the inspiration of contaminated air. In this locality it was probable that, as a rule, it found an entrance by means of contaminated air. The Croton water came from a long distance, and in itself was practically free from the danger of typhoid pollution. The invasion of the disease could generally be traced to some defect in sewage, and this was why it ought to be prevented. Typhoid fever seemed to be increasing in New York, and this he thought was due in part to the present deficient water supply, as well as to the defective sanitary provisions seen in many houses. Under the circumstances, we could only wonder that the disease was not more prevalent than it was.

In every case of typhoid fever to which he was called, the physician should ask himself, What is the cause of this? and insist on making a thorough examination for the purpose of finding it out. In almost every instance the cause could be found, and he thought that it was the duty of the Board of Health to institute such an investigation in every case reported to them. Since in

this way some local cause could almost invariably be discovered, a great deal might thus be accomplished in the way of prevention. In regard to typho-malarial fever, he found himself a little at variance with the author of the paper. He thought that this was a good rule which ought to be preserved, and that we frequently had seen in New York the combination of the typhoid germ with a malarial element. Dr. Janeway looked at the matter from an anatomical standpoint, but he viewed it from a clinical standpoint. He admitted that the typhoid lesions were found after death, and admitted that in certain malarious districts a large number of cases of fever were sometimes classed as remittent which were in reality cases of typhoid fever, because the latter distease had before been almost unknown in the region. But, at the same time, there was a class of cases which were better designated under the name of typho-malarial than any other. This was comparatively a recent term, but many years ago the distinguished Dr. Drake, in his work on the diseases of the Mississippi Valley, had described the same thing, or a very similar one, viz., malario-typhus.

DR. HOCHHEIMER said that, as Dr. Flint had expressed the opinion that the Board of Health should make a thorough investigation as to the cause in every case of typhoid fever reported to them, he was very glad to be able to say that the Board had already been doing this all through the past season, and as he had been one of the sanitary officers employed in this work, he had acquired a very considerable experience with the disease, and had been enabled to obtain a number of facts in regard to its present character in New York which perhaps might prove of interest to those present. He had studied it not in a limited locality or in an institution, but as it existed in private families in various parts of the city, and he had found it marked by a number of peculiar features.

The question of typho-malarial fever was one that came up frequently, and in endeavoring to trace back the cause to which this designation was applied by the attending physician, it was found that in a great many instances there had been three or four cases of fever in the same family. The first case was often comparatively mild, and it being taken for granted that it was malarial in character, not infrequently no physician was called in. It lasted pretty constantly for about four weeks, however, and was characterized by many of the symptoms of typhoid fever. When the second case became developed the physician was sure to be summoned. At first he was very likely to pronounce it malarial fever; but when by the second or third week distinctively typhoid symptoms had made their appearance, in order protect his former diagnosis, he would perhaps say that the disease had turned into typhoid, and would call the case one of typho-malarial fever.

The disease, as lately seen in New York, was very different from the typical typhoid fever described in the text-books. In nine-tenths of the cases not half of the ordinary characteristic symptoms of the affection appeared. As to the sanitary conditions and the proximate cause, the fact was very noticeable that the central portion of the city, say from Sixth Avenue to Lexington Avenue, was almost entirely exempt from the disease; and when cases did occur in this district, they could almost invariably be traced to a source of origin outside of the city. The great mass of the cases was met with along the rivers, both on the east and west side of town. Whether the emptying of the sewers into the rivers had anything to do with this, he was unable to say; but, aside from this, in almost every single instance, some sufficient local cause for the disease could be found. In this connection, it was a point of practical importance to note that no case of typhoid fever occurred in a house where the school-sink was employed, except in one or two instances where the apparatus had been allowed to become filthy or was out of repair. When it occurred on premises with privy-vaults, it was found that either the vault was not ventilated or the ventilating pipe had leaks in it. Sometimes, also, cases were found on the fourth floor of houses where the ventilating pipes were carried to the roofs of rear houses, and just on a level with the fourth floor of the houses in front. When the disease was met with in houses provided with water-closets, it was generally seen on the upper floors, where the water supply was most imperfect and irregular.

As to the age of the patients, the youngest child that he had seen with the fever was twenty-two months old, and, as a rule, it never occurred in young children unless they had been exposed to the danger of infection for a considerable time. By far the largest number of cases was found in those between the ages of twelve and forty; while between those of forty and sixty there seemed to be a remarkable immunity from it. Persons beyond the age of sixty, however, were very frequently attacked. There was one important question on which he thought it was desirable that some light should be thrown. It was taken for granted that the disease could be propagated only by a special cause derived from those suffering from it, and yet was not contagious. He should like to know whether it was possible for it to be conveyed by anything else than the dejecta of a patient.

DR. JANEWAY, in closing the discussion, remarked that while clinically there might be some ground for retaining the word typho-malarial, he thought the use of the term productive of harm, because it tended to keep both physicians and patients from taking proper precautions in regard to the disposal of the dejecta, which was a vital point in the prevention of the spread of the disease. On this account, therefore, as well as from the anatomical basis, he objected to the name, and thought that in cases in which such a designation seemed appropriate from the clinical characteristics, it was better simply to call the disease typhoid fever with a malarial complication. As the term was now commonly used, some physicians seemed to understand by it a disease which was neither typhoid fever nor malaria, but a vague and indefinite sort of an affection with some of the characteristics of each; and as long as the autopsies showed almost invariably the characteristic lesions of typhoid fever, he thought it very unfortunate that such loose ideas should prevail in regard to the matter.

CORRESPONDENCE.

"A YEAR'S WORK IN OVARIOTOMY."

To the Editor of THE MEDICAL NEWS.

SIR: Under the above heading there appears in THE MEDICAL NEWS of February 16, 1884, an article from the pen of my esteemed friend, Professor William Goodell.

In this article he misquotes me (of course, unintentionally) in the following sentence: "Whilst a very distinguished and successful British ovariotomist does not remove very large tumors—those which may weigh from sixty to sixty-five pounds—with extensive adhesions," etc. The word "very" is a mistake. I said, "does not remove *many* large tumors," etc. However, I am not aware that this British ovariotomist ever refuses to remove a tumor because it is large. In three months I spent with him (Mr. Lawson Tait), he removed but one large ovarian tumor; but he twice did hysterectomy with fibroids weighing thirty-eight and forty pounds respectively; during this time he was constantly removing the ovaries and tubes, frequently operating twice a day. One of the above hysterectomies, after which the patient recovered, was refused by Sir Spencer Wells. Very few operators get a long line of the same sort of cases, but Mr. Tait has the longest line of ovary and tube cases, and the shortest line of big ovarian cysts, of any man I visited in Europe.

In regard to the paper my criticism is offered in all kindness and with no desire to find fault. Taking into consideration that eleven of his twenty-five cases were done in a general hospital, and ten at their own homes, his results are simply excellent, considering the circumstances under which he operated. But out of the eleven cases done in the general hospital only one died, while of the ten done at home five died. Here is a chance to draw a conclusion that "home" for ovariotomy is worse than "general hospital." In his private hospital four cases were done with three recoveries.

This fact in regard to "home" as a place for ovariotomy is just about up to my own notions. If I had my choice between home and a general hospital as good as that of the University, I would take the hospital, but there are very few such hospitals in this country, and this one is not yet old enough to do its worst in abdominal operations. Several things have struck me as certain in regard to ovariotomy and its statistics in this country. One is that so long as the operation is done by ones and twos over the land, in homes and general hospitals, very little progress in good statistics will be made. Another is, *that when we follow the example of Keith and Tait, and prefer private hospitals, free from all general surgery and all diseases, in which to do our operations;* and when the cases are sent to a comparatively few operators thus engaged (keeping entirely out of general practice and pathological work), *we shall get just as good statistics as Keith or Tait show, and our climate will be relieved of a bad name.* Ovariotomies are usually poor pay cases; but no matter, some better results than some of us can show must be gotten or else *we ought to stop operating.* Last summer I lost every case I cut. (See *Medical and Surgical Reporter*, Feb. 2, 1884.) I was just as careful as I possibly could be under the circumstances. I changed the circumstances to a *private hospital on high ground, excluded all spectators* (*save those interested*), and, as a result, *every case I have cut since* has recovered *without a bad symptom*, and this remark applies also to a case done two weeks ago (*now well*), in which I removed the ovaries, tubes, and uterus above the vaginal attachment.

Yours respectfully,

R. S. Sutton, M.D.

Pittsburg, Pa., February 18, 1884.

HYPOSULPHITE OF SODA AND CARBOLIC ACID IN SEVERE CONTUSIONS.

To the Editor of The Medical News.

Sir: In 1869, I was summond to see Frank Reeder, a laborer in a saw-mill, who had received a severe injury by a log carriage, weighing about three or four thousand pounds, falling on his wrist and hand, which were very badly lacerated, the belly of the flexor pollicis protruding through a slit in the skin about the size of a large nutmeg. He was suffering great agony. No bones were fractured. I used cold water dressing, and gave him one-fourth of a grain doses of morphia, without affording him ease. On the second day he was no better; fearing that gangrene would set in, I ordered the following mixture:

℞.—Sodæ hyposulphit., . . . ℥iv.
Acid. carbolic. crys., . . ℥ss.
Glycerinæ, ... ℥ij.
Aquæ, ... Cj. M.

Sig.—To be used as a lotion, and to keep a cloth on the wrist and hand well saturated all the time.

In half an hour after using it, he was completely relieved, and passed a good night without any narcotic, and from this time he went on favorably without any trouble whatever, and in six weeks had full use of his hand.

In 1870, I was called to see a lad, about eight years old, with oblique fracture of the humerus above the condyles; it was almost a compound fracture, the point of the humerus coming so near the surface, that it caused a blood-blister to be seen under the cuticle. He complained a good deal, and as I disliked to use narcotics in one so young, I gave a prescription for the same lotion, and it had just as happy an effect in this case as in the previous one.

As I live in a town where there are about fifteen hundred men, who gain their livelihood by working in saw-mills and lumber, there is scarcely a day in which I do not use this lotion, and have never been disappointed in its effects. I could give you case after case, but it would be mere repetition, so I think it useless.

I have used it in erysipelas, and in the eruptions caused by *Rhus tox.* and the poison ivy, with good effect.

D. C. Hewson, M.D.

Orange, Texas, January 26, 1884.

THE OFFICE OF ASSISTANT SURGEON-GENERAL.

To the Editor of The Medical News.

Sir: On January 29, 1884, a bill (S. 1307) was introduced by Mr. Logan, to abolish the office of Assistant Surgeon-General of the Army. With perhaps one exception, the passage of this bill would affect, more or less, the status and promotion of the officers of the Medical Corps of the Army, and it should, therefore, be of sufficient interest to the medical profession at large to make at least some effort to prevent its passage.

In 1874, thanks to the efforts of the medical press and societies, the condition of the Medical Corps was much improved by adding a number of Colonels and Lieutenant-Colonels to the department, and it is believed

that the same feelings and views which existed at that time still prevail throughout the country. The prospects of Medical Officers of the Army are by no means too brilliant, and to limit promotion by abolishing the grade of Assistant Surgeon-General seems unjust.

It is claimed that the office is useless, and confers but an empty honor upon the incumbent. Bnt how is it that the late General Crane held the office for almost sixteen years, and who will deny that he did not fill the position with credit to himself and to his country? If there was work, and good, honorable and useful work to be done for one of the most faithful officers the Medical Department of the Army ever had, the same work must still remain, and the claim that the office is useless is not well taken. It may be true that the position confers but an empty honor upon the incumbent, but there are, no doubt, some medical officers who have grown gray in the Army who would be proud to bear that empty title as a slight recognition of the value of the services they have rendered to the Union. If the Assistant Surgeon-General is not now required at the seat of the Government, why not give him control of the medical affairs of the division commanded by the senior General officer? But do not abolish the office. Give it to one of those men who helped to carry civilization to the far west before some of us were born, and who administered to our wants, and those of our fathers, on many a bloody battlefield of the war of the Rebellion.

Foreign countries honor eminent men of the medical profession by conferring upon them medals, orders, knighthood, and nobility. We have nothing else to give them than that highest of all gratitudes, the thanks of the Republic, and for military surgeons, possibly that more substantial recognition, increased rank and pay.

What are a good many of our higher military positions, in time of peace, but empty titles? But who would think of abolishing these offices without crippling the military establishment, of which the Medical Department is undoubtedly a most important branch.

Yours respectfully,

CADUCEUS.

NEW INVENTIONS.

THE UVULATOME.

BY ROBERT W. KNOX, M. D.,
OF RICHMOND, TEXAS.

CLIPPING the uvula is one of the most common and simple of minor operations. Nevertheless, every practitioner encounters some difficulty in avoiding spasm, seizing the elongated organ, and severing it at the desired point. Indeed, with the ordinary methods, the uvula is usually clipped while in motion, and consequently it often occurs that the muscular substance is divided when the elongation is due, *not* to hypertrophy, but to the exuberant mucous membrane. When cut in this way, with scissors and forceps, the stump will be longer on one side than the other.

In order to avoid this last-named condition, and to facilitate the performance of the operation, I have devised the instrument here delineated. The handles are made long and curve upward when in position, thus facilitating an easy view of the throat. The special claim for the instrument is in the receiver beneath each blade, which is so arranged that one passes within the other, and thus all interference with the blades is avoided. No portion of the uvula or soft palate need be touched, except at *the very instant* of excision. No tenaculum or forceps is necessary, the severed portion of the organ being caught and retained by the instrument. The instrument is so simple, acting like an ordinary pair of scissors, that it is free from the uncertainty of the complicated uvulatome made after the plan of Physick's tonsillotome.

In addition to my own satisfactory experience with the instrument, it has elicited the approval and commendation of my friend, Prof. Dudley S. Reynolds, of Louisville, Ky., whose wide experience in laryngology entitles his expressions to special consideration.

This uvulatome was manufactured for me by Messrs. Tiemann & Co., of New York.

NEWS ITEMS.

CINCINNATI.

(From our Special Correspondent.)

CINCINNATI HOSPITAL.—The examination of candidates for the position of Interne to the Cincinnati Hospital, resulted in the appointment of Messrs. A. B. Phelps, J. Maloney, and F. W. Hendley, of the Medical College of Ohio; Messrs. R. Rover, B. J. Magee, and J. C. Oliver, of the Miami.

OHIO MEDICAL COLLEGE.—The annual contest for the prizes offered by Prof. W. W. Dawson, of the Ohio Medical College, occurred at the Good Samaritan Hospital a little more than a week ago. Prof. Dawson gives, each year, three prizes: one for the most expert bandaging, one for the best dissection, and one for the best anatomical drawing. The names of the successful contestants are withheld until the evening of the Commencement.

NATURE AND CAUSES OF CHOLERA.—A cablegram from Berlin, dated February 19, states that the German Sanitary Commission which was sent out to Egypt by the Imperial Board of Health to study the nature and causes, etc., of cholera, and which, after finishing its labors at Alexandria, was ordered to continue its investigations in India, has just forwarded a report from Calcutta, where it arrived some two or three months ago. The Commission discovered the cholera germ in a water-tank at Calcutta, and found in the suburban village, where the cholera appeared, the same microscopic organism which had been discovered in the lower intestines of cholera victims in Egypt.

YELLOW FEVER AT HAVANA.—Sanitary Inspector Burgess reports six deaths from yellow fever at Havana for the week ending February 9, 1884. He inspected

nineteen vessels during the week bound to United States ports, and disinfected those which had loaded at suspicious wharves.

MARINE HOSPITALS AT STATEN ISLAND AND MEMPHIS.—Mr. James, of New York, introduced a bill into the House last week, for the purchase of property for establishing a Marine Hospital on Staten Island, and Mr. Young, of Tennessee, for the completion of the Marine Hospital building at Memphis.

MEXICO WAKING UP.—It will be seen by the following action of the National Hygienic Congress, in session last November, as reported by Assistant Surgeon Main, that Mexico is falling into line, and now proposes to do something towards guarding her coast against imported diseases by establishing rigid quarantines, a measure always heretofore opposed by that country :

The Third Commission of the National Hygienic Congress has presented an extensive *Dictamen*, the result of which is to provide for the establishment of lazarettoes in the Republic. The document contains the following propositions:

1st. Quarantine stations to be established and built in all ports, for coasters and vessels of the high seas in the Republic,

2d. In the ports where it is possible to do so, the lazaretto shall be constructed upon an island; if not possible, it shall be on the mainland, at least two kilometres distant from any population, and in a contrary direction to the prevailing winds with respect to the port.

3d. But in its construction the following conditions should be observed :

a. To be built upon a vegetable soil, when practicable, beneath which may be found an impermeable subsoil, and with sufficient declivity to facilitate drainage.

b. It should not be near a mountain ridge or other eminence that may in any degree impede the free circulation of the prevailing winds.

c. It should have at its undisputed disposition a sufficient supply of living and potable water.

4th. Each lazaretto shall consist of three departments; one for the sick, one for observation, and one for baggage and merchandise; and each one with its correspondent servants and employes.

5th. These departments should have the following conditions:

a. Proportionate capacity to avoid agglomeration.

b. Convenient orientation, locality considered; and so disposed and planned as to reap the richest benefits of the prevailing currents.

c. The distance between each department shall be at least two hundred metres; and the department of observation shall be first to receive the wind, by its relative situation, respecting the other departments.

d. The perfect non-communication between the three, and with the port.

e. The department for the sick is to be a model of St. Elol Hospital, of Montpelier, as nearly as may be in all respects.

6th. Persons in apparent health are not to be detained at Vera Cruz in the wards of observation, but are permitted to go at once to Oriyaba, and there suffer quarantine before going farther into the interior, unless it is desired to return immediately to the coast.

7th. This discipline is to be respected in other ports and infected places, provided the topographic conditions and means of communication permit it.

8th. All persons coming from places where cholera, smallpox, yellow fever, or pest, or any other infectious diseases exist, shall be submitted to the lazaretto regulation.

SURGEON-GENERAL HAMILTON BEFORE THE PUBLIC HEALTH COMMITTEE OF THE HOUSE.—Surgeon-General Hamilton, of the Marine-Hospital Service, by invitation, appeared before the House Committee on Public Health on Thursday, the 14th inst., to answer certain charges preferred against him by Colonel Waring, Secretary of the National Board of Health, viz., that he "he had been unskilful, injudicious, and unsuccessful in his quarantine work," and that "in his efforts to control public and official opinion he had been guilty of misrepresentation." To refute the first charge Dr. Hamilton read a letter from the Board asking him to give them the benefit of his experience in quarantine work, and such suggestions as to the course to be taken by the Board in carrying out the law; to examine the blanks and forms now in use by the Board; and to obtain such aid, counsel, and assistance as he might be disposed to furnish the Board. He produced another letter from the Board showing that their original regulations for the management of quarantine, which President Hayes failed to sign because so unskilfully drawn, were amended in accordance with his suggestions, and after passing through his hands were signed by the President. He then denied that he had made misrepresentations in seeking to control public opinion. He stated that the President of the National Board of Health had written a letter to Speaker Carlisle setting forth at length his grievances against the Marine-Hospital Service, and requesting the appointment of the persons he named as members of the Committee on Public Health. Dr. Cabell, who was present, stated that he had asked Mr. Carlisle to place men on the Committee who would attend the meetings and who took an interest in health matters, and that at the request of Mr. Carlisle he had put his application in writing, but disclaimed any intention of packing the Committee.

Several members of the Committee spoke upon the subject, Mr. Davis, of Mass., saying that he had been approached by Dr. Cabell at the Riggs House, who, finding he had served on the Massachusetts Board, said he would be a proper person to be placed on the Public Health Committee, and asked him if he would serve. He answered declining; he was then asked, if appointed, would he serve, and that he told Dr. Cabell he hardly thought he would decline if the Speaker appointed him, but that if the Committee now saw fit he would tender his resignation. Dr. Hamilton said he did not believe the Committee had been packed, but he wanted to show the attempt had been made. He said, however, that Dr. Smart, Secretary of the Board, had packed the Public Health Association, at Indianapolis, and produced the circular letter addressed by Dr. Smart to members of that Association. He characterized these plans of the Board as "injudicious."

Dr. Hamilton defended the quarantine management by the Marine-Hospital Service, and produced affidavits and statements from citizens in various towns of Texas,

together with a letter from the Governor, approving the work. He then spoke of the management at Pensacola by the National Board, through its protégé the old Pensacola Board, and stated that the latter had been presented for negligence and maladministration by the Grand Jury. Also, that the National Board approved a requisition for $2000 from Pensacola after the epidemic had disappeared, which money was divided up among friends of the Board. If not dishonest, this was at least "injudicious." The sinking of several vessels of the "Mississippi fleet" by the nautical member of the Board, was characterized as "unskilful." He then laid the responsibility of the Pensacola epidemic of 1882 at the door of the Board, who through its protégé let the disease into that city. He showed that Colonel Waring, its present Secretary, had been employed by the Board to investigate and write essays on sewer-traps, etc., at the time that gentleman held patents on that very subject, reading a list of said patents to the Committee. He considered this "injudicious." He showed that Dr. Verdi, a member of the Board, had been paid $300 for an eight and a half page essay, three and a half pages of which were made up of an editorial taken from the London *Times*, and figures from the Bureau of Statistics —also "injudicious." There was much more of the same sort of material brought forward by Dr. Hamilton which our limited space will not permit us to give, and he informed the Committee at its adjournment that he was not nearly through. He has been invited to continue his argument at its next meeting.

ARMY MEDICAL OFFICERS.—A bill was reported favorably last Tuesday by Senator Logan from the Committee on Military Affairs, to define the title and duties of certain officers of the Medical Department of the Army. It provides that that department shall have two grades of officers, one grade to be known as assistant surgeons-general with the rank, pay, and emoluments of colonel, and another, to be known as deputy surgeons-general, with the rank, pay, and emoluments of lieutenant-colonel.

TO COMPENSATE AN ARMY SURGEON.—The Senate last Tuesday passed a bill to compensate Dr. Edward P.Vollum, Surgeon, United States Army, in the sum of seven hundred dollars for loss of personal effects by wreck, in 1856, of a vessel on which he shipped as a passenger under detail from the Secretary of War.

VIVISECTION IN GERMANY.—At the request of the Minister of Public Instruction, the Medical Faculty of Berlin has recently given the following opinion as to the necessity of vivisection: That vivisection is necessary for investigation and instruction, and that without it no further advance in physiology is possible; nor can that opinion and judgment be acquired by the students which is only to be arrived at by an insight into the performance of the important functions of life. Furthermore, a series of experiments on animals is necessary and indispensable for medical instruction if the laws of nerve-conduction, digestion, circulation, etc., are to be effectively understood; and their comprehension by the physician is necessary to enable him to check hemorrhage, or perform any other operation which is necessary for the restoration of health. But especially, in later years, does the science of medicine owe to experiments on animals much of the light thrown on the causes of human disease, as well as upon the means for preventing them. The proper disposal and disinfection of excrementitious matters would also be impossible without these experiments. Experiments on animals are therefore of enormous importance and great value for the State and society, as well as for science.

To this paper are signed the names of Du Bois-Reymond, Virchow, Westphal, Liebreich, and other distinguished scientists.

THE PROPOSED NATIONAL PHARMACOPŒIA.—*The Journal of the American Medical Association* says of the bill recently introduced into Congress for the publication of a *National Pharmacopœia*, that "the method of supervision and preparation provided in the bill secures as much freedom from local and partisan influences, and imparts to it as much of a truly national character, as is possible, while the publication by the government removes it entirely from the field of financial strife or competition. We hope individual members of the profession in every State will use what influence they have with their representatives in Congress, promptly, in favor of the passage of the bill."

THE INTERNATIONAL HEALTH EXHIBITION.—The outline of the International Health Exhibition, to be held in London this year, includes six groups, and extends to sanitary appliances for schools, workshops, dwellings, food, dress, and in all to about sixty classes in detail. There will be held with it an International Congress on Health and Education. The Hygienic Exhibit at Berlin last year was visited by nearly a million of people, and proved a financial success, notwithstanding the fire which consumed the first building.

NEW JERSEY STATE BOARD OF HEALTH REPORT.—The seventh annual report of the New Jersey State Board of Health has valuable articles on "School Hygiene," "The Protection of Schools from Contagious Diseases," on "Health Resorts," "Kerosene," "Malt Beverages," "Milk," "The Care of Homes," and on "Modes and Places of Interment." A list of all physicians who have registered under the law of 1880 and its supplements, shows about 1800 practitioners in the State, with all forms of diplomas, certificates, and licenses.

THE SEWERAGE SYSTEM OF BOSTON, as recently completed, was first outlined in 1875, and has been chiefly executed by J. P. Davis, C. E., and his engineering staff. The plan is that of intercepting sewers and pumpage. The pumping station is at Old Harbor Point, and Dorchester Bay is crossed by a tunnel. The whole is constructed after the most careful details, and Boston will no doubt be greatly benefited by a system, the guiding formula of which is, "The sewage shall pass in a continuous current from the houses until it reaches its destination in deep waters far away."

FOOT AND MOUTH DISEASE is very prevalent in Great Britain. The whole number of animals attacked for the year ending December 31st, is given by Fleming's *Veterinary Journal* at about 440,000. The disease has arrived here two or three times by importation, and once within a year at Philadelphia, but was quickly

recognized and isolated. We have recently seen two animals inoculated with the disease for experimental purposes.

GLANDERS has again broken out in the South Orange car stables, near Newark, N. J., although the State has a special law requiring the destruction of diseased horses, and over sixty in this stable have been killed.

GASTROSTOMY IN THE SEVENTEENTH CENTURY.—MR. JAMES DIXON, in a communication to the *Medical Times and Gazette*, February 2, 1884, states that on July 9, 1635, Daniel Schwaben opened the stomach of a male and removed a knife which he had swallowed. No attempt was made to close the wound in the organ, which is described as spontaneously shrinking together. The external wound was closed by five sutures, and a poultice was applied. Soup was taken by the mouth on the day of the operation, and a powder administered. The patient recovered and lived several years.

DR. WEIR MITCHELL is the author of a story now appearing in *The Atlantic Monthly*, which has a medical interest.

A RECEPTION TO DR. PARVIN.—The Alumni of the Jefferson Medical College gave recently a reception to Prof. Theophilus Parvin, at the St. George Hotel, Philadelphia.

"THE DWELLINGS OF THE INDUSTRIAL CLASSES IN LIVERPOOL," "The Rehousing of Outcast Glasgow," and "The Homes of the Poor in Dublin," are subjects of valuable papers in the *Sanitary Record*, by Drs. Forwood, Stoddard, and Cameron. They show what wonderful sanitary and moral blessings have resulted from the removal of whole streets of rookeries, and from the model lodging-places and other tenements.

VITAL STATISTICS OF PARIS.—The quarterly summary of the Bureau of Vital Statistics of Paris, for the quarter ending December 31, 1883, shows the work done by the Night Medical Service during that time. The total number of patients receiving medical attention was 1773, and the average number of visits per night was 1937. Of the patients, 34 per cent. were men, 51 per cent. women, and 15 per cent. children under 3 years of age. Among the patients visited were 226 cases of labor; diseases of the respiratory system, 264 cases; diseases of the digestive system, 148 cases; diseases of the nervous system, 333; accidents, 149. Among the number, 50 were reported dead before arrival of the physician.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending February 9, 1884, indicate that typhoid fever, tonsillitis, intermittent fever, diarrhœa, and measles have increased, and that remittent fever, erysipelas, and inflammation of the bowels have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending February 9, and since, at ten places, scarlet fever at fourteen places, and measles at ten places. One case of smallpox was reported in Bath Township, Clinton County, February 10.

NOTES AND QUERIES.

THE ENDORSERS OF THE NEW CODE.

To the Editor of THE MEDICAL NEWS.

SIR: In the last number of your Journal, it is stated editorially that "Dr. Roosa is reported to have said that letters had been received from the best men of many States, urging New York State to stand firm in shaking off the shackles of the so-called National Association, and promising that other Societies would follow the example."

A regret is then expressed that Dr. Roosa did not read those letters, and you also state that the *Record* had not been willing to produce letters which its editor had received, endorsing its course "in its advocacy of freedom in consultations," but the hope is expressed that the letters to which Dr. Roosa referred "may not share this sad fate," but "yet see the light of day."

In answer to all this, or to that part of it which concerns me, I beg that you will allow me to say: *First.* That for this time I am reported by THE NEWS with entire correctness, both as to letter and spirit. *Second.* The letters to which I alluded, cannot be produced and published at the call of THE NEWS, because they are private letters. In my opinion, to publish them would be to violate a code which I hold very dear; the unwritten code that obtains among gentlemen. *Third.* To publish these letters would be to invite for the writers the same kind of attacks upon their integrity and motives, that have been so persistently made upon those who have "thrown off the shackles" of the Judicial Council of the American Medical Association.

When the writers of those letters are ready to face the persecuting spirit which dropped the name of Alfred C. Post from the roll of the American Surgical Society, and which in New York City impotently threatened to boycott and ostracize the opponents of the Old Code, they will, undoubtedly, write and speak to the profession at large. Although I must decline to furnish you with the names of those who have written the letters for which you ask, I will say that the writers of them are prominent medical men in the States of Maine, New Hampshire, Connecticut, Massachusetts, Rhode Island, Pennsylvania, Virginia, Ohio, Missouri, North Carolina, and California. It also gives me much pleasure to inform you that I have indirect but reliable assurances from several well known physicians in Philadelphia, that they will, in due time, endeavor to induce the profession in that city to shake off the *Old Code*.

I am, sir, yours very respectfully,

D. B. ST. JOHN ROOSA, M.D.

20 EAST 30TH ST., NEW YORK CITY,
February 16, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 12 TO FEBRUARY 18, 1884.

PERIN, GLOVER, *Lieutenant Colonel and Surgeon.*—Medical Director, is granted one month's leave of absence with permission to apply at Division Headquarters, Missouri, for an extension of one month.—*S. O. 16, Department of Dakota*, February 9, 1884.

To be Assistant Surgeons.—With the rank of First Lieutenant to date, December 3, 1883. WILLIAM D. DIETZ, WALTER W. R. FISHER, WILLIAM STEPHENSON, ADRIAN S. PALHEMUS, JOHN L. PHILLIPS, REUBEN L. ROBERTSON, WILLIAM C. BORDEN, EDGAR A. MEARNS, GUY L. EDIE, WILLIAM D. CROSBY, WILLIAM L. KNEEDLER, CHARLES M. GAUDY, CHARLES S. BLACK, JAMES E. PILCHER, ALONZO R. CHAPIN, —*S. O., A. G. O., Washington*, February 11, 1884.

BREWSTER, WILLIAM B., *First Lieutenant and Assistant Surgeon.*—Resignation accepted to date, February 7, 1884.—*S. O., A. G. O., Washington*, February 11, 1884.

WILSON, GEORGE F., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Walla Walla, W. T.—*S. O. 14, Department of the Columbia*, February 5, 1884.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIV. SATURDAY, MARCH 1, 1884. No. 9.

ORIGINAL ARTICLES.

THE GEOGRAPHICAL DISTRIBUTION OF URINARY CALCULUS, WITH AN INQUIRY INTO ITS CAUSES.[1]

BY E. L. KEYES, M.D.,
OF NEW YORK.

IT is a fact universally recognized that stone occurs more frequently in certain portions of the world than in others, but a satisfactory explanation of the fact has not yet been established. It is customary to ascribe it to the hard waters of the affected districts; but investigation disproves the validity of such a claim. Agnew[2] states that in certain valleys in Lancaster County, Pennsylvania, of limestone formation, the water is very hard, being strongly impregnated with lime; yet calculus is not common in these valleys, and he joins former writers in the very apposite reflection that it is difficult to understand how calculi, most of which are composed of uric acid, should be stimulated into growth by the use of alkaline lime-water.

Civiale, whose statistic researches on this subject were very thorough, has written,[3] "Dr. Warren, of Boston, recently told me that stone is very rare in Massachusetts, and is almost unknown in those localities where granite rock abounds, while it is found occasionally at other points, where the soil is calcareous; but this alleged influence of the nature of the soil upon the production of calculous disorder is an hypothesis only admitted to explain facts, the true cause of which is not evident. Several of the localities from which I have received statistical documents possess the granite formation, yet, in spite of this, calculus is far from being a rare disorder there. I may cite among others certain points in Sweden."

Again, speaking of the stone cases reported from the Department of Var, in France, he says: "The malady seems to be equally divided among all classes of society. The nature of the soil, which is flinty and granite on the coast, and calcareous in the interior, does not appear to make any sensible difference in the distribution of the cases."

Cadge,[4] of Norwich, England, on the other hand, ascribes the great frequency of calculous—urid acid—disorders in the district to the hardness of the waters. Prout distinctly states his belief that hard waters are a factor in the production of stone, and many excellent urinary pathologists and practical surgeons agree in this way of thinking. Reginald Harrison[1] tries to explain it on the ground that hard waters interfere with digestion, and in that way modify the conditions of the solids in the urine and the state of the colloids. He adduces in support of his argument the frequency of stone in the bladder in the young among the poor about Norwich, and the fact that milk is scarce and dear, and quotes from the essay of Cadge that the frequency in this district of the occurrence of stone in children "will be found in strict accordance with the difficulty of producing milk."

In this connection, as to the liability of drinking-water to stand in a causal relation to calculous disorder, it is proper to call to mind a fact vouched for by Roberts,[2] and only to be explained on the ground of coincidence, or of cause and effect. He says: "The suburban district of Hulme supplies considerably fewer cases of stone to the Manchester Infirmary since the pipe-water has replaced the old pump-water supply."

It is proper also to refer in this context to a curious indirect means by which the drinking of water may prove a source of stone formation. Zancarol,[3] surgeon to the Greek Hospital at Alexandria, Egypt, states that the natives drink unfiltered Nile water, and imbibe the *Distoma hæmatobium;* that the animal and its ova can always be found in the urine, and among the layers of stone as extracted from the natives; and that the latter suffer frequently from calculous disorder. Foreigners, on the other hand, who drink only filtered Nile water, do not often have stone, and their urine does not contain the distoma or its ova.

Roberts[4] also ascribes the frequency of calculus in Egypt to the presence of the minute urinary parasite, the *Bilharzia hæmatobia.*

But to return to the water question, pure and simple, Mastin[5] takes the other side of the argument, showing that in Kentucky and Tennessee sandstone districts, where the water is very soft, calculous disorders are common, while they are just as frequently encountered in the limestone areas of the same region. Where hard water is drunk in Alabama, where stone is quite uncommon, Mastin says there have been only fifty to seventy-five operations performed upon the natives of that State since its settlement in 1817. Most of the cases have originated in a belt of country running east and west, and including Tuscaloosa, "a pure sandstone region with the softest and best water in the State." Mastin further adds in connection with the question of stone in Alabama: "The northern

[4] Op. cit., p. 275.

[5] Causes and Geographical Distribution of Calculous Diseases. Transactions of the International Medical Congress, Philadelphia, 1877, p. 609.

and eastern sections abound in blue limestone, and the water is very strongly impregnated, yet we rarely, if ever, hear of a case of gravel or limestone within these limits. Again, in middle and southern Alabama, the base of the soil is what is known as "rotten limestone," and the water strongly alkaline; this is also the case in eastern Mississippi, and still we have been unable to obtain reliable information of even a half dozen cases of stone having ever occurred in these regions.

He cites also Dr. Guild, the leading surgeon of Tuscaloosa, as asserting that all his stone cases have come from the sandstone district, where soft water is used.

Therefore it seems fair to assume that whatever influence hard water may have in the production of stone must be exercised in some secondary manner, as by deranging the digestion (if it operates at all, which may be considered doubtful).

Probably no country is entirely free from areas in which stone formation is relatively prevalent, but the distribution of these areas seems to be arbitrary. Thus in England, where stone is quite common, the eastern counties of Norfolk and Suffolk appear to be most afflicted. It is noteworthy that as many cases occur each year in Norfolk among its 438,656 inhabitants (Cadge), as in all Ireland with a population of 5,412,377. The northern counties of Ireland and of Scotland furnish more cases than the remaining portions of those countries.

Calculous disease abounds in France, as Civiale has clearly brought out, in Teneriffe, in Iceland, in Egypt; it is also very common in Russia. Klein[1] states that cases of stone sometimes constitute a fifth of all the patients under treatment in the hospitals of Moscow.

Estlander,[2] on the other hand, shows that primary calculous disorders are almost unknown in Finland, the University Hospital case-books containing only one Finlander, with a stone originating in the kidney, during a period of forty-four years. There were cases of phosphatic stone with paralyzed bladders, etc. Civiale[3] notices a similar immunity in Christiania, where, out of thirty-two hundred and eleven patients in hospital during four years, only one had stone; while in the hospital of Gothenburg, in Sweden, a hospital of sixty beds, there had been no stone case since the existence of the hospital—a period of fifty years.

Fayrer,[4] a well-known authority upon medical questions in India, states that stone is very frequently encountered in the northwestern and central provinces of that country; five hundred and fifty-four cases were cut for stone during a single six months in 1863. In Lower Bengal stone is rare. Fayrer[5] says that lithotomy had been performed only about one hundred times in the Medical College Hospital up to 1873. Harris[6] confirms the fact as to Bengal, and ascribes the prevalence of the malady in the northwestern provinces to the cold winds which blow from the Himalayas, and to a heavy unfermented bread used by the natives. Dr. Garden's testimony from the Sarahunpore Dispensary is corroborative of the frequency of stone in India. Mastin[1] refers to Curran for authority in stating that Hindostan is exceptionally rich in stone cases. Vandyke Carter[2] speaks for Bombay and the great prevalence of oxalate of lime calculi in that region. He thinks that stone is more common in Bombay or western India than in the southern or Madras Presidency. Mr. Dudgeon,[3] of Pekin, who succeeded Kerr in China, informs us that in China, at Canton and Takow in Formosa calculus is found, but apparently not elsewhere. At Pekin the water is full of lime; at Canton very soft. Kerr[4] also states that Canton furnishes the stone cases of China, the missionary hospitals of twenty years' existence in Ning-Po and Shanghai, and at Pekin and Hangkow for eight years, having supplied attendance to thousands of patients, but not to a single case of stone. The Rev. P. Parker, it appears, founder of the Medical Missionary Society, performed the first lithotomy of which there is any modern record in China.

In Norway, Sweden, Denmark, Syria, and Spain stone is not very common. In France and Holland it is abundant. In Austria, Germany, Italy, Persia, and Syria it is reasonably frequent in occurrence.

In Mexico, Central and South America, and Australia, so far as known, the disease is not common. Livingstone failed to find syphilis or stone among the natives of Central Africa.

In North America, in the United States, the greatest number of stone cases originate in the central districts—Tennessee, Kentucky, Ohio, Indiana, Missouri, Western Pennsylvania, and Virginia. In Utah it is said to be common. Authorities differ as to Georgia and North Carolina. In the Northern, Eastern, Gulf, Southern, and Western States calculus is uncommon, as it is also in the Canadas and British possessions.

These inequalities of distribution are not satisfactorily accounted for by any peculiarities of race, food, habits, soil, climate, temperature, or water.

I am speaking of primary acid stone formation; secondary phosphatic stone, due to obstructive and catarrhal maladies of the genito-urinary tract, or to the presence of a foreign body, is found equally in all climates and in all conditions of life provided only the proper etiological factors are present locally in the individual.

Why, then, does the fact exist that certain portions of the earth's surface are more fertile in stone cases than other portions?

Race may have something to do with it, even under the same conditions of climate, etc. Gross,[5]

[5] Op. cit., p. 168

among the lithotomies reported during a certain period in different Southern States of mixed population, found the proportion to be one negro to six whites. Rayer states that the negro escapes in Egypt, while the Arab suffers. Mastin[1] has collected three thousand and thirty-nine reliable lithotomies in America, and finds only one hundred and two put down to the negro and thirty-one to the mulatto. Mastin further notices that gout is very rare among the black people in the United States, and he quotes Winterbottom as vouching for the same fact for the native Africans around Sierra Leone. These statements appear to have a direct bearing upon the question. Reports like those of Livingstone concerning the negroes of Central Africa are not in point, since the districts did not contain a population of mixed races for comparison.

Climate.—That climate alone should influence stone formation seems improbable. There is no striking analogy of climate between Moscow and Kentucky. Temperate zones seem to be most afflicted, yet the cold winds of the Himalayas and the general boisterousness of the winds about Norwich, England, have been accused as contributing to the stone tendencies of those regions. The central districts of the United States, however, are not preëminently windy. In France, Civiale found the proportion of cases in the Var district the same inland and on the coast. The New England shores are subject to dampness and boisterous northeasterly gales, yet the calculous malady is not common there. Soldiers and sailors are reported by all who have given attention to statistics to be remarkably free from stone, yet their life is surely one of exposure, and the reason for their immunity must rather be set down to the fact that most men practising those professions are between the ages of twenty and forty—a period of life most exempt from stone.

Social Condition, *Habits*, and *Occupation* are not paramount as etiological factors of stone, although they have a certain bearing upon it. Civiale distinctly states that, in his collections in France, social position made no difference in the relative number of cases found in a certain district. Undoubtedly there are more stone cases among the poor than among the wealthy; but the latter class is very small in any community, and nearly all the cases of the poor go to the hospitals for operation, where they are sure to be recorded, while the wealthy escape tabulation to a certain extent.

In New York there is very little tendency to stone formation. During nearly thirteen years' connection with active surgical work in the Bellevue and Charity Hospitals, I have found in my service only two cases of stone; all the others with which I have had to do in hospital have been sent in by myself from outside. By far the greater portion of stone cases which I have had to do with have been found among patients in easy circumstances; but this, of course, is accidental, and by no means indicates that more wealthy than poor people have stone in New York.

[1] Loc. cit., p. 618.

Thompson,[1] however, remarks that he does not "know any disease which marks more distinctly or more curiously its relations with class than this. So common is stone in the children of the poor, comparatively speaking, that at Guy's Hospital, surrounded as it is by a very large neighborhood, densely populated by some of the most badly nourished classes of the community, quite one-half of the cases admitted are children. Among the same classes, however, it is rare at the other end of life, very few elderly workingmen in London being afflicted with it. On the other hand, among the well-to-do and well-fed, while almost never found in childhood, it is comparatively common in advanced age."

Alcohol.—It is doubtful that alcohol will produce stone without other predisposing agencies. In large cities alcohol is consumed freely; but no statistician has noted a special prevalence of stone among adult dwellers in cities over the relative average among the natives in the surrounding counties. An abundance of liquor is consumed in Scotland and in Ireland; doubtless as much as, or more than, in England, yet the latter locality is the favorite one for stone. Some wines, like Rhine wines, as Sömmering has pointed out, being charged with bitartrate of potash, rather militate against tendencies to stone; but sweet, fermented wines, champagnes, and malt liquors, since they increase the tendencies toward uric-acid formation, undoubtedly aggravate any predisposition to stone formation which may already exist.

Food alone cannot materially promote stone formation by its quality, although, where the tendency exists, it may be intensified by the quality of the food. Thus, in India, Vandyke Carter found oxalate of lime nuclei among the calculi of the rice-eating natives; but it is not starch as food that causes stone, or the potato-eating Irishman would be prone to it, which is not the case; nor is it rice-starch, or the Chinaman would be as constant a stone producer as the Indian, which again is not the case.

In Europe and America, uric acid stones are the rule; but if a meat diet caused stones, the latter would be much more common in cities, where much meat is consumed, than in the surrounding country, which again has not been noted as a fact.

Abundance of milk as a diet has been supposed to avert tendencies to stone, and probably this is true, but alone it is an insignificant factor. Indigestion again has been accused as causing stone formation, but if indigestion alone were a main cause, surely the disease ought to be rampant in New England, where hot bread, pie, and rapid eating, with accompanying bad teeth and dyspepsia are the order of the day among the people—and yet stone is very rare in New England. A possible reason for the relative frequency of oxalate of lime in the calculi of India, may perhaps be found in the well-known disturbances of the liver which are said to be common in that climate, the cause of

[1] Clinical Lectures on Diseases of the Urinary Organs, sixth edition, 1882, p. 67.

oxaluria being often, in this country at least, associated, if not identical, with functional hepatic disturbance.

Constitution.—It is probably not doubtful that gout and rheumatism increase any existing tendency there may be to stone formation, because these diathetic conditions are accompanied by acidity of the urine, as a rule, with a tendency to abundant excretion of uric acid, urates, and the like. A gouty individual, leading a sedentary life, drinking beer and champagne, and eating a highly nitrogenized diet, especially if he does not exercise, has a little dyspepsia, and is constantly kept anxious about his business, is exactly in a fit condition to form stone easily. Cases of kidney colic with the passage of small acid concretions are constantly furnished by this class of individuals.

Allowing then, if the foregoing representations are accurate, that water, climate, soil, occupation, exposure, digestion, alcohol, and food are not responsible for the geographical distribution of stone, granting some weight to race and social condition, and considerable influence to the rheumatic diathesis, what factor remains to be considered, for surely these alone are not entirely sufficient?

The only one which seems capable of filling up the gap is heredity.

As gout is hereditary, so are the tendencies to stone. I have, at present, under observation a family in which three generations, all living, have strong and constantly outcropping tendencies to the appearance of fine, uric-acid gravel. The baby of four years, and the grandfather of seventy, manifest it about equally. Mr. William Cadge,[1] in discoursing recently to the Norwich Medico-Chirurgical Society about a woman with sacculated bladder and stone, mentioned that the patient's father had died after lithotrity, and that her brother, living in Buckinghamshire, was then said to be suffering from stone.

The most celebrated recorded instance of inherited tendency to stone, so far as I am aware, is that reported by Mr. Clubbe,[2] of Lowestoft, where six children all had stone, the father and mother passed quantities of uric acid, the grandfather, grandmother, great-uncle, six uncles, four aunts, and a cousin, all had had attacks of gravel, or had been cut for stone.

It seems to me not very improbable that hereditary tendency lies at the bottom of the regional distribution, and largely accounts for the peculiar geographical localities of stone. Generation after generation growing up in the same region of country and intermarrying would naturally reproduce and intensify any such physical trait as a tendency to stone. I am aware that it has been claimed that strangers going to Norwich have developed stone, having shown no tendency to it in their own land; but it would take a large array of such facts to constitute anything more than a coincidence.

In former years of slow locomotion, the few who emigrated married others with different tendencies, and so failed to spread the habit, or married others with like tendencies, and thus established new areas of stone formation.

Food, drink, and surroundings may have intensified or modified these natural tendencies more or less, but that the essence of the geographical distribution of stone (primary acid stone) lies in intensified and reduplicated hereditary predisposition seems to me at least plausible in lack of a better general explanation.

With modern improvements in rapid transit, and facility and cheapness of locomotion, it seems at least possible that the centres of stone formation may be somewhat broken up, and by more general and mixed marriages the disease become more extended in geographical area, but less active.

NEURALGIA OF THE NOSE AND PHARYNX.

By LOUIS JURIST, M.D.,
INSTRUCTOR IN LARYNGOLOGY AND RHINOLOGY, POST-GRADUATE COURSE, AND CLINICAL CHIEF IN THE LARYNGOSCOPIC DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL.

In looking over various works treating of the neuralgiæ in general or in detail, the entire neglect of nasal and pharyngeal manifestations, or the greatest variation of opinion concerning them, was immediately apparent.

Dr. Anstie describes a "rather common and extremely troublesome" form of pharyngeal neuralgia, occurring usually in hysterical females, accompanied by one or two painful points in or behind the tonsil, pains radiating into the tongue and along the course of the carotid, with the accumulation of much thick mucus and reflex muscular movements. Dr. J. Solis-Cohen considers the affection "rare and its causes obscure." Dr. Morell Mackenzie quotes Tuerck as describing six cases, but thinks some of them approach more nearly to simple hyperæsthesia. He himself has seen many instances of the disease in women between the ages of twenty and forty, gives no detailed account of the symptoms, praises scarification should there be hyperæmia, and recommends the local use of tincture of aconite in all cases. Dr. Elsberg, in an essay on "Sensory Neuroses of the Throat," states that he has met with nine cases of neuralgia in fifty-eight of sensory disturbance, and adds that "true neuralgia unquestionably occurs."

My own experience is limited to the following five cases, with a sixth still under observation. I am inclined to believe that Drs. Mackenzie and Anstie considered the morbid sensations so often complained of by women as typical neuralgia, or they would hardly have spoken of them as "common" or "troublesome." True neuralgia, especially of the earlier periods of life, can be relieved or controlled; subjective nerve symptoms depending so often upon the mental state of the patient, yield but slowly, if at all, to our best-directed efforts.

CASE I.—Mrs. A. C., æt. 40. Her hereditary history is excellent, and she claims to have been in good health until some years after marriage, when

she had become much reduced in strength by a quick succession of pregnancies and overwork. She has suffered for the last six months—she applied to me in December, 1882—with frontal pain and earache, fulness in both nostrils and darting pain in the post-nasal region. There was no discharge. Examination showed a reddened, tumefied nasal mucous membrane. The use of the probe caused sneezing and an increase of pain in all the parts complained of. There was tenderness in front of the ear, and at the emergence of the supra- and infra-orbital nerves, but the region over the frontal sinus was insensitive.

CASE II.—Miss A. B., æt. 15, anæmic and extremely nervous. Hereditation good. She had an attack of chorea, due to fright, at the age of twelve, from which she recovered after three months' treatment. Menstruation set in at the age of fourteen, and has been regular ever since. She came to be treated for catarrh and earache of one month's duration. She complained of obstruction of the left nostril and violent paroxysmal pain, which seemed to dart from the middle ear into the left side of the nose. There was considerable tumefaction of the mucous membrane covering the middle and inferior turbinated bones of that side, with hyperæsthesia and some redness. The parts were free from secretion, but she spoke of a discharge "like water" when the pain was at its worst. The auditory canal was normal and not sensitive; membrana tympani perfect. The teeth of the upper jaw were much decayed. There was a sensitive point over the infra-orbital foramen, and one on the side of the nose.

CASE III.—Mrs. P., æt. 50. No family history obtained. Her sister, however, has been in an asylum under treatment for insanity—attributed by the patient herself to "womb disease." Mrs. P. has been under my observation for the past three years, during which time she has exhibited a variety of symptoms fairly attributable to the menopause in a patient with a neuropathic tendency. She had the first attack of trifacial neuralgia two years ago, and has suffered two outbreaks since, always accompanied by the same manifestations: lachrymation, severe conjunctivitis, photophobia, dryness of the left nostril with inability to breathe through that side, and the occurrence of a profuse serous discharge with the subsidence of the attack. Examination during two attacks has shown a tumefied inferior turbinated bone. The use of the probe caused a distressing attack of sneezing. During the interval her nose is perfectly clear.

CASE IV.—Miss S. W., æt. 26. Paternal antecedents good. Her mother, three male members of whose family have died of apoplexy, suffered with migraine in early adult life, but has recently had, apparently in its stead, three severe attacks of neuralgia of the lumbar plexus. Miss W. developed trifacial neuralgia of a severe type at the age of twenty-one, after a period of much mental and physical strain. During her last attack, I noticed a small, circular, hyperæmic, and extremely sensitive elevation on the left anterior palatine fold, red and painful malar and mental points with grayness of the eyebrow and hair of that side. Articulation and deglutition were difficult, the patient declaring her muscles stiff, living on liquid food, and maintaining an almost absolute silence. This condition lasted three days.

CASE V.—Mrs. W. S., æt. 60, ignorant of her family history, was seen by me, in consultation, on September 26, 1882. She was stout and well preserved, with no indication of senile decay. For the previous six weeks she had had most excruciating paroxysms of pain, at intervals of five or ten minutes, throughout the entire day and night. Large doses of morphia had given her an occasional respite. She described the pain as beginning in the throat, darting into the ear, and down into the neck. Each paroxysm (and I witnessed a number) was accompanied by involuntary contractions of the facial muscles. Gastric irritability, due to the morphine, interfered greatly with my examination. I found the parts normal, with the exception of a bright red spot on the left anterior palatine fold, pressure upon which promptly caused an attack. I repeated the manipulation several times with the same result. Treatment, which will be discussed below, relieved her promptly, but a recurrence took place four months later of a much milder type.

The treatment of Cases I. and II. embraced an alkaline spray to satisfy the patients that the catarrh was being attended to, and the administration of gelsemium in small, but oft-repeated, doses until full physiological effects were produced, and then keeping them influenced for two or three days longer. Case III. was put on the same treatment, without the spray. Duquesnel's aconitia, in the dose of one two-hundredth grain, gradually increased until the well-known tingling and numbness were complained of, was employed in Cases IV. and V. with admirable results. The average time of treatment of the neuralgia proper was about ten days, a tonic treatment being instituted afterwards. The nutritive disturbances occurring in these cases were of the utmost interest. The frontal pain or fulness, hyperæmia or tumefaction, or both, and the secretory changes may be fairly attributed, I think, to the disturbed innervation—to the influence, perhaps, of the so-called "vaso-motor" and "trophic" systems.

1210 WALLACE STREET, PHILADELPHIA.

A CASE OF EXTENSIVE BURN, UNHEALED AFTER SIX YEARS, PERMANENTLY CURED BY MASSAGE AND SKIN GRAFTING.

BY FRANK C. WILSON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE HOSPITAL COLLEGE OF MEDICINE, LOUISVILLE, KY.

IN February, 1883, I was consulted by Miss L. P., of Va., as to the possibility of relieving an unhealed burn of about six years' duration, the history of which I give in her own words:

"I was burned on the night of the 11th of September, 1877, about 10 o'clock, by the explosion of a kerosene oil lamp. I had gone to my room; undressed; and was writing near a bureau on which

the lamp was placed. While writing I heard a spurt from the lamp and noticing a flare in the blaze, I immediately arose to my feet, and at that instant the explosion occurred, throwing the burning oil on my left arm and side and igniting my clothing. My father heard the explosion and my scream from his room, immediately beneath mine, and came to my assistance in a second or two. He attempted to tear my clothing from me, but, finding he could not do so, wrapped me tightly in a pair of woollen blankets, in order to smother the flames. This, of course, drew the burning clothing, saturated with hot oil, closely to my arm and side, though it at once extinguished the flame. He then carried me down stairs, and upon removing my clothing, it was found that I was very badly burned on the left arm from above the elbow to the ends of the fingers, and down the left side extending to the spine, and from the waist to a little below the hips. It was apparent from the first that the arm and hand were the most severely burned, the skin and flesh hanging from the arm in shreds, leaving the bone exposed in several places. The burns were then covered with lard and flour, and a sheet was wrapped around me. In this condition I remained for three hours before the arrival of the physicians, who administered chloroform to alleviate and deaden the intense suffering, removed the lard and flour, and applied linen cloths saturated with a mixture of linseed oil and turpentine. By the time the effects of the chloroform wore off I was greatly relieved by this application. This treatment was continued, and was the only one used for a long time. In a few days the sores commenced suppurating, and the flow was so excessive that daily renewal of the cloths, and redressing was necessary; to be able to endure this, I had to be chloroformed, and for one hundred and twenty consecutive days I was put under the influence of it to have the operation repeated. The only position I could occupy was on my back; thus lying on the sore on the back in a single bed in the centre of the room, the arm being placed on a pad and suspended by a cord from the ceiling. The arm was very red and swollen to three times its natural size, while the hand seemed to be one entire scab. It was three months before there was any evidence of the burns on the body healing, but the hand and arm still remained obstinate, without any signs of improvement. Some time in January, 1878, the treatment was changed, and vaseline was used as a salve. The sores on my body began to heal, and by the first of March I was able to be taken up and put in a rocking-chair. This was of great benefit to the burns on my back, relieving the pressure, and they healed so rapidly that by the first of July I could wear a dress, by leaving out the left sleeve.

"On the 4th of July, I went to Lynchburg, Va., to consult Dr. ——, who examined the hand and arm thoroughly and prescribed cauterizing with nitrate of silver. I returned home and attempted to follow his prescription, but it was so painful and seemed only to inflame and aggravate the sore, that I gave it up in a week or two. In December, 1878, I went back to Dr. ——, and placed myself under his care until I should be cured. I cannot remember the various remedies he used the first month; there were a number of powders, salves, etc., none of which suited the hand at all. At last he commenced using a lotion, the name of which I never knew, giving at the same time internally, Fowler's solution of arsenic. The hand and arm at once began to heal, and by the middle of May he discharged me, thinking the cure permanent. I came home, but it was only a short time before the hand began to burn and break out in small sores, and by the first of July it was almost as bad as ever. I immediately returned to Dr. ——, but nothing he did seemed to check the spreading of the sores, and in October of 1879 I came back home with the arm almost entirely healed, but the hand a perfect mass of sores. In this condition it remained for one year, when my general health became so bad from the constant drain on the system that on the 16th of October, 1880, I went to Richmond, Va., to consult a distinguished surgeon of that city, who, after an investigation of the case, seemed to think he could permanently relieve me. He had the hand poulticed until all the thick scab was removed, then applied absorbent cotton saturated with solution of hydrate of chloral, twenty grains to a pint of water, The hand healed rapidly under this treatment, and I began to strengthen, taking, as a tonic, tincture of iron with strychnia, etc.

"I left Richmond on the fifteenth of December, and once more flattered myself that my hand was cured, but as soon as the warm weather set in, it commenced breaking out as before. I consulted my Richmond physician by mail, and he prescribed a continuation of the chloral and tonic, but as these failed to have any effect, I went back to him in January, 1882, but he did not seem to think much else could be done for it, and, had I urged it, would have readily assented to its amputation as the best method of relief. I returned home and continued the treatment with the chloral and cotton until January, 1883, when I went to Louisville, Kentucky, for treatment."

When I took charge of the case a careful examination revealed the following condition. The arm and forearm from above the elbow to the wrist showed large cicatrices in many places adherent to the deeper structures and even to the bone. The elbow could not be straightened beyond an angle of one hundred and fifty degrees, due, in all probability, to ossific deposit in the olecranon fossa, which had no doubt been exposed by the burn. The hand, which was flexed at the wrist, was healed over the dorsal surface, the skin presenting a shiny, glistening, and unhealthy appearance. The finger nails were like rams' horns, mere masses of horny tissue, piled upon the ends of the fingers. Upon the palmar surface of the hand and several of the fingers were large suppurating sores, which had remained in the same condition for more than a year. At times they would heal a little, only to break out again. The little and third fingers were very much flexed by cicatricial contraction, and the width of the hand very much narrowed by the approximation of the thumb and little finger. The circulation in the fore-

arm and hand was exceedingly poor, the pulse at the wrist being scarcely perceptible. Her general health was bad, appetite poor, countenance pale and anæmic. She suffered greatly with a burning sensation in the hand.

I determined to pursue the following line of treatment: 1st, to improve the circulation and develop the muscles by thorough massage; 2d, after thoroughly cleansing the suppurating surfaces by a poultice, to insert numerous skin grafts; 3d, to divide the cicatricial contractions; and, 4th, by daily manipulation gradually to restore the use of the joints. Placing her in charge of a skilful manipulator, I had the satisfaction of finding a most marked change in two weeks, the pulse becoming strong and full, the skin taking on a much more natural appearance, and healthy nail tissue showing itself at the roots of the nails. I then applied a poultice for twenty-four hours, clearing off all the dried scabs, leaving a raw, granulating surface upon which I inserted eight or ten grafts taken from the skin of a young rabbit. Several of these adhered, forming little islets of skin. I next inserted a few grafts from the human skin: but chiefly relied upon grafts taken from the inner membrane of a perfectly fresh hen's egg. A number of these were inserted and many of them adhered, so that in a few weeks the entire raw surface was covered with sound cuticle, and the entire surface of the hand presented a much more healthy appearance. The horny masses upon the extremities of the finger were about half pushed off by the growth of the new and healthy nails. As the cicatrization proceeded, Madame Lager followed it up by her massage, even developing the interossei muscles.

With the return to the normal and healthy condition of the tissue, the sense of constant burning which had before been so annoying and depressing, entirely disappeared.

When the surface had completely healed, I divided the cicatricial contractions, strapping the fingers to a dorsal sole-leather splint, so as fully to extend them, until the raw surfaces left by the burns should heal. This was hastened by grafting as before, and in a few days the splint was removed. It was found necessary to divide a second time the contraction of the little finger, and in order to lessen the tendency to subsequent cicatricial contraction the cut was filled with a sponge graft. Although this healed over much more slowly than the others yet it answered the purpose well.

Systematic and regular manipulation of all the joints was then practised and the electrical stimulation of the muscles added, so that gradually the use of the hand was recovered. She passed through the hottest part of the summer without any tendency to break out as it had done every year previously, and she was sent home about the middle of August with instructions to continue the regular manipulation of the joints with the daily use of the battery, with which she was provided. October 15th, she writes that the hand continues to strengthen daily and that she can do anything she wishes with it.

The first point to be noticed in this case is the marked benefit to be ascribed to the massage treatment, which, by stimulating the circulation of the limb, so improved the nutrition of the part that much more healthy tissue was formed, as shown by the growth of natural nails and the disappearance of the shiny, glistening look of the skin.

To the poor circulation no doubt was due the constantly recurring ulceration of the surface.

2d. The use of the three forms of skin grafts gave the opportunity of testing their relative merits. Of the three, I much prefer the egg membrane, as being more readily obtained, and one egg, which must be warm and fresh, will supply any number of grafts needed. A large proportion of those inserted adhered, forming islets, which by their coalescence covered over the entire surface.

3d. The recovery of the use of the muscles and joints was greatly promoted and hastened by the daily manipulation and the use of the faradic battery.

Louisville, Kentucky, October, 1883.

ON A METHOD OF ABDOMINAL TRACTION, AND ITS APPLICATIONS.

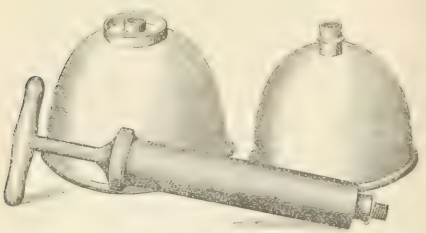
By HENRY HARTSHORNE, M.D.,
of Philadelphia.

Some time since, I exhibited before the College of Physicians of Philadelphia a simple apparatus for abdominal traction; having especially in view its use as an aid in producing artificial respiration. My attention had been called to the incompleteness of the means commonly employed for that purpose, by their failure in two cases of drowning which I was so unfortunate as to witness at Atlantic City, N. J. Easy experimentation on my own person satisfied me, as it may anyone, that Sylvester's method (the best in use) has very little *compulsory* power in expanding the lungs. One may, without the slightest difficulty, effect *expiration* while the arms are raised backward and far over the head, and *inspiration* while they are being brought down and pressed laterally against the ribs.

Considering the large amount of force readily exercised by the diaphragm in what is called "abdominal" as distinguished from "thoracic" respiration, it is reasonable to suppose that, in asphyxia from any cause, respiration may be prompted and assisted in renewal by *drawing the viscera away from below the diaphragm.* Such is the intention of the apparatus which I now propose to describe. It consists, first, of a tube or pump, not unlike, in shape and size, to an ordinary enema syringe of the old-fashioned kind; holding, however, somewhat less than a pint, for lightness; and having a cross-piece at the handle, for greater firmness in traction. It is constructed as a *two-valve* exhausting pump; so that, by drawing upon it again and again, a firm hold may be taken and kept.

Secondly, the tube is adjusted to a large cup or metallic bowl; designed to be applied to the abdomen. I have had two sizes of bowl made, so as to suit bodies of greater and less width and stature. One bowl is seven and a half inches across its outer rim, and five inches deep; the other is six inches across, and three and a half inches in depth. Either may be affixed to the exhausting pump for abdominal

traction. My first thought was to use a *one-valve* pump, so as to *alternate* rapidly the elevation and depression of the abdominal walls; but it was soon found that, unless with a pump so large as to be



Scale one-fifth inch = 1 inch.
Abdominal Tractor.

unmanageable on account of its weight, the lifting of the viscera by one draught of the pump will not be sufficient to answer a good purpose. By trial on a living body, I find that the exhausting pump and bowl above mentioned will take a very strong hold of the abdomen, and exert a great lifting action upon its contents.

No case of drowning or other asphyxia having come under my observation since the instrument was constructed, I have had so far to content myself with its trial upon the living body, with normal respiration, and some applications of it to dead subjects. The latter, however, on account of the bodies having been semi-solidified by preservative injections, were not satisfactory in determining what such traction may do towards effecting artificial abdominal respiration. This yet awaits an opportunity of fair trial. The least that may, in my judgment, be expected of it is, that it may render valuable aid to the Sylvester method; just as *counter-extension* does to *extension* in the reduction and treatment of fractures. The two methods may be combined with perfect facility and convenience.

More positive ground of confidence appears to me to exist, in regard to the application of a similar mode of abdominal traction to the treatment of *strangulated hernia* and some forms of *intestinal obstruction*. This is not a new proposition. Authors mention it as having been put in practice by Anton Nuck, the eminent anatomist and surgeon, professor in the University of Leyden, near the end of the seventeenth century. It is said to have been a method sometimes in use by Russian practitioners; and allusion to it was made in an English medical journal within a year or two, the reference to which has recently escaped my search.

Slight reflection will show that the reduction of a femoral or inguinal (of course not an umbilical) hernia must be promoted by forcibly abstracting the mass of the contents of the abdomen in a direction opposite to that of the protrusion. This is the *rationale* of the common expedient of raising the patient's heels high above his head, which I have known to be quite effectual in practice.

Also, it is evident that if, in a case of *intussusception*, we could seize either the received or the receiving portion of the gut, and draw upon it, we should almost certainly relieve the invagination. While this is not *sure* to be done in every case by abdominal traction, it affords a greater *probability* of such a result than any other mode of treatment without laparotomy, and hence it is worthy of careful trial.

My apparatus was made by A. H. Wirz, of Cherry Street, Philadelphia, and will be at the service of any practitioner who may desire to use it in fitting cases.

GERMANTOWN, PHILADELPHIA.

HOSPITAL NOTES.

NEW YORK EYE AND EAR INFIRMARY—SCHOOL OF OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

(Aural Service of DR. SAMUEL SEXTON.)

Reported by ROBERT BARCLAY, M.D., Assistant Surgeon.

FOREIGN BODIES IN THE EXTERNAL AUDITORY CANAL.

THE frequency with which troublesome cases of foreign body in the external auditory canal are met with, and the great importance of keeping in mind the anatomical relations of the parts to these intruders lest harm should result to the organ of hearing during efforts at removal, makes the subject one of particular interest to the general practitioner as well as to the specialist. Thanks to the large attendance at the aural clinic of the Infirmary, examples of this kind are numerous enough to give a very fair idea of the subject. In presenting this matter, some of the following cases were shown to the students, and Dr. Sexton offered such practical remarks as the different cases suggested.

Foreign bodies are not often met with in the ears of very young infants, unless put in by playmates—a difficult feat on account of the collapsed state of the canal in these subjects. Older children, however, frequently introduce them themselves. The entrance (meatus) to the canal is often, especially in children, naturally contracted by the elastic fold of its posterior border which comprises that portion of the cartilage forming the bottom of the concha and the beginning of the canal. When foreign bodies are slipped beyond this constriction, they are indefinitely retained, since they cannot fall out again of themselves, nor can they be removed by jarring the patient's head. In syringing for their removal, escape at this point is difficult, and should, therefore, be facilitated by drawing back the auricle, and completing the extraction by means of the hook or forceps. Illumination by means of the head-mirror is a *sine qua non*.

Piece of chalk in ear of child aged three years, remaining two days, no morbid symptoms; removed with forceps.

L. S., aged three years, came to the Infirmary August 7, 1882.

On the afternoon of August 5, the patient pushed a

small square piece of chalk into the right external auditory canal. The mother of the patient subsequently attempted its removal, and, after failing, brought the child to the Infirmary. Examination showed a white body in the right external auditory canal.

Dr. Sexton, with the aural foreign-body forceps, easily removed this white body, which proved to be a piece of chalk. No morbid symptoms were reported, and there were no physical signs to indicate any injury to the ear.

Half bean in ear of boy aged five years and seven months; ineffectual attempts at removal; under anæsthesia, bean removed in fragments; painful mastication.

G. F. F., aged five years and seven months, came to the Infirmary, August 26, 1882. On August 25, the patient, while at play, put half a Lima bean into his left external auditory canal, and, in attempting to remove it with his finger, pushed it farther inward. Shortly afterwards, he attempted to remove it with a pin, and pushed it still further from the meatus. The patient then went to the family physician, who tried in vain to remove it with instruments. He subsequently made another unsuccessful attempt the same day. He then gave the mother a liquid which he ordered her to drop into the patient's ear as fast as it evaporated, telling her to return with the patient the following day. Instead of doing so, she came to the Infirmary, August 26. There had been no discharge from the ear. It was found unadvisable to attempt removal of the foreign body on account of the exceedingly restless condition of the patient.

On August 28, after the patient had been anæsthetized by the house-surgeon, Dr. Sexton removed the three fragments of bean, the bean having previously been broken. These pieces of bean were quite soft.

On August 31, the canal was tender and red, and the patient irritable. Mastication was painful. The fact that the lower molars on both sides were carious was significant.

The patient improved under treatment, and was subsequently discharged.

Round button in ear of girl aged five years, remaining two months; ineffectual attempts at removal; removal accomplished under anæsthesia.

B. S., aged five years, came to the Infirmary January 8, 1883. Two months ago the patient put a round china button into her left external auditory canal, where it has remained ever since. Attempts were made at one time by the family physician to remove the foreign body, but proved unsuccessful, and caused great pain. Examination showed a foreign body in the left external auditory canal.

The patient having been anæsthetized by the house-surgeon, the foreign body was removed by foreign-body forceps, and proved to be a round china button. No harm was done by the operation.

Cotton-wool wad in ear of man aged sixty-six years, with cerumen; removal with syringe; deafness relieved.

J. G., a carpenter, born in Germany, aged sixty-six years, came to the Infirmary June 4, 1883. The patient has been deaf in the left ear for the past six months, and says he knows no cause for it. He has experienced no pain, and the ear has not discharged. At the time he first noticed this deafness, he swabbed the ear once with water on a swab of cotton, and, as he says, does not remember having left any of the cotton in the canal after drying it. The deafness subsequently increased in the left ear. The right ear gives no abnormal subjective symptoms.

Examination showed a moderate amount of cerumen in both canals, which are large. Syringing brought away the cerumen, and from the left canal a small wad of cotton also. Relief was complete.

Bug in ear of woman aged twenty-one years; remaining one-half day, with intermittent tinnitus; removed with syringe.

M. C., aged twenty-one years, came to the Infirmary June 11, 1883. This morning, on awakening, the patient says she "felt the legs or wings of something moving around in her right ear." This sensation alternately ceased and recurred. She has had at no time any subjective tinnitus aurium, nor impairment of hearing.

Examination shows a small black body at first on the posterior inferior quadrant of the membrana tympani, but later on the anterior inferior, as it has changed its position. Syringing brought away the dark body, which proved to be a small bug.

The alternate disappearance and recurrence of tinnitus aurium, corresponding to the rest or movement of the insect, are significant; and the patient could hear perfectly well even when the insect was at rest or moving upon the membrana tympani.

Flies in ear of patient aged seven years, with otorrhœa following scarlet fever; removal with syringe.

H. V., aged seven years, came to the Infirmary July 23, 1883. Four years ago the patient had scarlet fever, lasting for about five weeks, which was followed, for one or two weeks, by a discharge from both ears. At the end of that time, it ceased in the left ear, but has continued in the right to the present time. The discharge is very offensive. Some slight impairment of hearing was found in the right ear. Examination showed the right external auditory canal filled with pus. On syringing, three flies were removed with the pus. A polypus was now visible at the inner end of the canal.

From this time, the patient improved; the polypus was removed; and under the treatment subsequently maintained, the patient finally recovered.

Cases of insects in the ear with otorrhœa are seen very frequently at the infirmary. The one cited above is a fair type of this class of cases.

Two cherry-pits in ear of girl aged four years; one removed by mother with hairpin; the other removed at Infirmary with syringe and forceps.

L. S., aged four years, came to the Infirmary August 13, 1883. The patient's mother stated that she removed from her right ear, two weeks ago, a cherry-pit. While cleaning her right ear yesterday morning, August 12,

the mother inflicted pain, of which the patient complained; this pain has continued ever since then.

Examination showed another cherry-pit deep within the right external auditory canal, with congestion of canal walls. The left ear was normal. Syringing brought the cherry-pit to the vicinity of the meatus, and Dr. Sexton's assistant, Dr. Adolph Rupp, removed it with the foreign-body forceps.

Discoid pencil-tip in ear of boy aged eight and one-half years, remaining six days; great pain; repeated ineffectual attempts at removal by several physicians; wound of drum-head; removal under anæsthesia with improvised hook and forceps.

N. C. M., aged eight and one-half years, residing in Saugerties, N. Y., came to the Infirmary October 25, 1883. On October 19, the patient put a foreign body into his right external auditory canal. His father could himself discern the foreign body lying there, and after vainly attempting to extract it, took him the same day to the family physician. Attempts were made by him to remove it with an earspoon. The attempts were unsuccessful, and caused immediate and subsequent pain. On the next morning, October 20, the attempts at removal were repeated, an earspoon and forceps being employed. The attempts were futile, and caused the patient great pain, which now continued, with intervals of relief. Glycerine was ordered to be put into the canal whenever the patient complained. This order was obeyed, and glycerine was applied thrice during the day and once during the night. On the following morning, October 21, the patient was taken to Albany, N. Y., where a well-known surgeon was consulted, and given control of his case. He first syringed the ear very persistently, but in vain, and then attempted removal with an earspoon and forceps. The attempts were attended with pain, hemorrhage, and failure. The seance lasted one hour and a half, and no anæsthetic was employed. After these unsuccessful attempts, this physician advised the patient's father to permit no one to use instrumental aid, or attempt removal, but to drop sweet oil and chloroform into the canal, and that the foreign body might escape without further interference. Another physician in Albany saw the patient on October 22, and made unsuccessful attempts to remove the foreign body, using syringe and forceps, causing pain, which subsequently became constant.

The patient was then brought to New York, and came to the Infirmary on October 25 seeking relief. Examination showed that he had had nasal catarrh for several years, and that he was a mouth-breather. Both of the superior six-year molar teeth were carious. The left membrana tympani was dull and humid in appearance; the canal of this side contained some dried cerumen.

The right external auditory canal, on being examined, showed a foreign body embraced rather tightly in the swollen tissues, and smeared with blood, epithelium, etc., from previous efforts at removal. Its size and shape could not be determined, although, from the touch of the probe, it seemed to be very hard. It lay well down in the cul-de-sac beyond the isthmus of the osseous portion of the canal. The gentleman who first saw this case at the Infirmary made an attempt at removal by syringing, without avail, however. Dr. Sexton had the patient anæsthetized, and, after cleansing the parts by light syringing and subsequent drying with cotton-wool, proceeded to employ his own foreign-body forceps for the removal of the intruder. It was found, however, that, after seizure by the forceps, although very considerable force could be exerted, so large was the bite of the instrument (the part seized being, as it afterwards appeared, the circumference of the foreign body) that its grip was not sufficient to insure success. A hook was then improvised by bending a silver probe near one extremity, and this was passed sidewise between the object and the superior wall of the canal, then turned, so that its hook engaged against the inner surface of the substance to be removed, when very considerable traction was made, with the result of bringing what appeared to be the broken-off ivory tip of a lead pencil into the cartilaginous portion of the canal, whence its removal was completed by forceps.

It is worthy of remark that it was stated to the operating surgeon that the foreign body was an ovoid or spheroidal pebble, which was misleading to the extent that the forceps were unnecessarily abandoned, since, had it been known that the object was a flat section of a bone or ivory pencil-tip, a little manipulation would have soon discovered the flat-sided surfaces, which could have been easily held in the grasp of the forceps. It was determined, when operating, to bring the foreign body away even at the risk of considerable laceration of the wall of the external auditory canal, which is well known to heal very readily.

Slight hemorrhage followed the operation from the laceration of the canal; but, unfortunately, it was found that the numerous attempts previously made had resulted in wounding the middle ear, and it was deemed unwise to send the patient home until he had recovered from the results of this injury. A letter from his parents, written in November, reports no further trouble since their return home.

Stone in ear of boy aged seven years, remaining six months: ineffectual attempts at removal; removal with syringe and curette.

O. S., born in Germany, aged seven years, came to the Infirmary December 3, 1883. Last summer a playmate put a small stone into the patient's right external auditory canal. It caused some pain at the time; and whenever he tried to lie with his right ear upon the pillow, the pain became intolerable. On November 30, his mother, in trying to clean his right ear with a hairpin, felt it scratch the stone. At the same time, this caused the patient such pain that he cried out. His mother, after attempting in vain this morning, December 3, to remove the stone with a hairpin, and having hurt the patient a great deal, brought him at once to the Infirmary for relief.

The patient states that, except when the stone is interfered with, he experiences no distress. He hears with his right ear a low voice at a distance of fifteen feet.

Examination showed the external auditory canals to be rather large, affording an unusually distinct view of the passage. The right one contains a little cerumen, but the stone can be plainly seen just beyond the lumen. The patient seems to be of a courageous nature, enduring manipulations very well, and Dr.

Sexton decided to operate without placing him under an anæsthetic.

At first, the hooked curette, as made by Mr. Ford,[1] was employed, but a slight movement of the child's head caused the pebble, which lay loosely in the passage, to be carried further inward; the foreign-body forceps were then employed, with a similar result, the object being pushed a little further inward with each attempt. The stone now lay on the verge of the isthmus, and further attempts would have resulted in carrying it over into the cul-de-sac, from which place its removal would have been far more difficult. The auricle was now drawn well backward and outward, and a strong but small stream of warm water was thrown from the syringe underneath the stone; the return stream carried it somewhat outward, and a second stream brought it out until it met the slightly constricted lumen, whence it was completely dislodged with the curette. It proved to be a stone, light colored, very smooth, somewhat ovoid, but flattened. The wall of the canal was found slightly abraded at the isthmus. The membrana tympani was intact and healthy, though slightly reddened from the effects of the syringing.

On December 10, examination showed a little cerumen in the canal, which is rather greater in quantity than ordinary. The points of abrasion are healed. There is no irritation remaining in the canal. The membrana tympani is intact and normal.

Remarks.—Some practical suggestions were made by Dr. Sexton to the class in regard to the removal of foreign bodies. There should never be undue haste or precipitation in the efforts at removal: the disadvantages of a neglect in respect to this were shown in some of the cases brought to notice. In young and restless children, it was quite often necessary to administer an anæsthetic before beginning operative procedures. The operator should first carefully ascertain the exact location of the object and its size and character; and as to this matter, the statements of the patient or friends should not be implicitly relied on, as they were frequently misleading; sometimes the foreign body was found to be quite different from what it had been stoutly asserted to be.

Regarding the choice of instruments to be employed, Dr. Sexton advised that when the patient was old enough to keep quiet, and the object was found just within the lumen, the hooked curette before alluded to was usually alone sufficient; but even in such a case as this, if the foreign body had been started further in on being touched it was well to direct a smart stream of warmed water into the canal, well to one side of the stranger, if possible, and this should be quickly followed up until successful, not forgetting that the child must usually be firmly held by a competent assistant during the operation. Should the foreign body, however, be found well down in the cul-de-sac and impacted, as is too often the case, from previous unsuccessful efforts, syringing may be unavailing; then the foreign-body forceps will often be useful—indeed they are of the greatest value when the object is impacted anywhere in the canal, since, when held in their bite, very great traction can be made. When the hard, or smooth and hard, nature of the object prevents a secure hold being thus obtained, the hooked curette is the more serviceable instrument, for it can be, in nearly all cases, forced between the object and the walls of the canal, when, from its firm hold—the teeth being set so that, on withdrawal, they become fastened or firmly impinge against the object—effective traction can be made. Of course, when a firmly impacted body has once been started, efforts should not be relinquished until successful, even though the canal be considerably lacerated, for such wounds are generally found to heal very promptly. When the foreign body lies in contact with the drumhead, it requires great tact and dexterity to avoid injury of that delicate structure, but in the great majority of instances the operation may nevertheless be safely performed. In these difficult cases of deep impaction, it is often found that the foreign-body forceps will grasp hard and smooth objects more successfully than would be supposed, and patient effort in this direction should not be too quickly relinquished. The surgeon must *under no circumstances try to fix the forceps without distinctly seeing what he is about.* If the parts are moistened with blood, mucus, etc., this should be carefully wiped away before proceeding. Sometimes the bleeding may be checked by light syringing with *hot* water before wiping the parts. Should the operator carelessly poke these forceps about in the neighborhood of the drumhead in efforts at seizure, he may easily lacerate that membrane.

MEDICAL PROGRESS.

Administration of Medicines through the Air-passages.—On November 13, 1883, Dr. Sandras read a paper before the Académie de Médicine on "Antimicrobial Medicamentous Inspirations or Inhalations." His very interesting experiments have led Sandras to hope that medicamentous substances introduced into the respiratory apparatus act either directly and locally by immediate contact with the injured portions of the organs, or indirectly on the nervous system and on the whole organism, after having gotten into the circulation through the lungs.

In concluding his paper, Sandras suggests that this is a new way opened for the introduction into the organism of medicines which the stomach cannot retain in certain cases. This method has already given very happy results, both in diseases of the respiratory and of other organs. The medicines are administered by spray from an inhaler.—*L'Abeille Méd.*, January 14, 1884.

A Baby without Arms or Legs.—The *Enciclopedia Medico-farmaceutica* states that this teratological case is now interesting the profession in Madrid. It is that of a little girl, five months old, which was born without arms or legs. The thoracic and abdominal cavities are perfectly formed. When born, it seemed doubtful whether it could survive, but at present it is in a very healthy condition. Its first teeth have just appeared, and it weeps and laughs just as other children.—*Progrès Méd.*, February 2, 1884.

Preventive Inoculation with Attenuated Charbon-cultures.—At the meeting of the Académie des Sciences, on December 3, 1883, M. Chauveau presented

a note on preventive inoculation with charbon-cultures attenuated by the method of rapid heating. M. Chauveau's studies on this subject, with the assistance of M. Wosnessenski, especially as regards the respective *rôle* of heat and oxygen in the attenuation of virulent cultures, have demonstrated the enormous preponderance of the first of these agents and the possibility of producing, by the exclusive use of rapid heating, attenuated cultures practically utilizable for preventive inoculation.

Between May, 1882, and September, 1883, M. Chauveau has inoculated a large number of sheep with his special culture liquids, the spores of which were attenuated by heat at 176° F. None of them have died, and he has assured himself in every case, by a third culture, that the harmless spores preserved their activity. But it is still more interesting to know whether these sheep really acquired an immunity, whether the inoculation had exercised a preventive influence upon them. Of this there is no doubt, for revaccination with very strong virus had no effect.

It is certain that all the subjects have not the same resistance; the greater part of those in which the first inoculation produced only slight effects were highly susceptible to the second inoculation with strong virus: those, however, which were made sick by the first vaccination were not susceptible. Chauveau now uses Pasteur's method of double inoculation, which is as follows: Instead of heating *en masse* all the *vaccinat* (the liquid for inoculating) contained in each receptacle, he makes two equal parts, one of which is heated to 176° F., and the other kept as it is. The latter is called the second vaccine. The first—that heated—was tried on ten sheep; none of them died. The second experiment was unavoidably delayed, but only one died. Three weeks afterwards the remaining nine were inoculated with very virulent blood, but with no bad effect. They had, therefore, acquired perfect immunity.—*Gaz. Hebdom.*, December 14, 1883.

PILOCARPINE.—M. HUBERT LAVRAND has recently made quite an extended study of the physiological and therapeutic action of pilocarpine.

Pilocarpine may be given in the form of the nitrate or hydrochlorate, by hypodermatic injection, in doses of gr. ⅛ to ¼. Its double diaphoretic and sialagogue effect is the indication for its use. In affections commencing with a chill, in asthma and the dyspnœic attacks in emphysema, it is highly useful. Though it acts less rapidly than morphia as a sedative, the effect is more lasting. It may be employed as a useful adjuvant in the treatment of diphtheria.

Pilocarpine will sometimes arrest an acute pleurisy in the beginning, and very often has a favorable influence upon it. In ocular therapeutics it may take the place of eserine as a myotic, and may be employed by instillation. In acute nephritis, under the influence of pilocarpine the symptoms rapidly improve, and in many cases the affection is promptly cured. Pilocarpine has a beneficial action on uræmic accidents, whether puerperal or scarlatinal. Chronic parenchymatous nephritis is benefited by pilocarpine in all its stages, especially when there is uræmia; but the more recent the lesion, the more efficacious is the drug. It is also efficacious in chronic interstitial nephritis.

The only contraindication to the use of pilocarpine is an advanced cardiac lesion; it causes arythmia and a diminution of the arterial tension. It has been used successfully in a large number of cases of obstinate hiccough, in persistent neuralgic pains, and in alopecia; it is a powerful antidote against belladonna and atropia poisoning, and may be given, in these cases, in larger doses.

Rabuteau has lately shown that pilocarpine and ergotine are antagonistic, the first acting as a vaso-dilator poison, the second as an excitant of smooth muscular fibres.—*Progrès Méd.*, December 29, 1883.

SALICYLATE OF BISMUTH IN TYPHOID FEVER.—PROF. VULPIAN has recently shown the value of Desplat's study of the antipyretic action of the salicylate of bismuth in typhoid fever. In the hands of Prof. Desplats, this remedy has given very satisfactory results (see an abstract of his paper in THE MEDICAL NEWS, August 4, 1883, p. 124). In doses of ℈iv to ℥ijss, administered several times a day during the course of the disease, it seems to have a decided abortive action; and after the disease has fairly set in, it lightens the symptoms and moderates the gravity of the affection.

It is difficult to determine its precise mode of action. Does it act on the ferments contained in the blood and certain viscera? Or does it act on the spinal centres and moderate the temperature? These points are not definitely determined, but its antiseptic action in organized ferments is very powerful, as shown by experiments in the laboratory, which permit us to think that it acts on the materials contained in the intestines of typhoid fever patients; for its insolubility permits it to reach the lowest portion of the intestinal tract without being absorbed. Its action corroborates the ideas of Klebs and Eberth as to the two distinct stages in the evolution of typhoid fever; the first characterized by an intestinal lesion purely local, and due to the development of microorganisms; and a second, of general auto-infection, with localization in the different organs.—*Progrès Méd.*, December 29, 1883.

MALFORMATIONS OF THE HEART IN THEIR RELATIONS TO THE PATHOLOGY OF CYANOSIS.—At the close of a paper on this subject, DR. DAVID NEWMAN, of Glasgow, draws the following conclusions: It appears that the most important cause of cyanosis is obstruction to the flow of blood to or from the right side of the heart, and that the degree of the discoloration depends upon—

1. The time at which the obstruction became sufficient to give rise to cyanosis. The earlier the symptoms appear the more marked are they likely to be.

2. Free communication of venous and arterial blood in so far as it determines the resistance to the flow of blood to or from the right chambers of the heart, and the amount of blood carried to the lungs.

3. The amount of compensation established by a patent foramen ovale, or ductus arteriosus, or by a collateral pulmonic circulation.

4. The nature of the vessels and integuments—the thinner the vessels and other textures the deeper the hue.

5. The degree of hypertrophy of the right ventricle and the condition of the tricuspid valves.—*Glasgow Medical Journal*, February, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, MARCH 1, 1884.

THE TREATMENT OF DIPHTHERIA.

THE wide-spread prevalence of diphtheria, the necessary interest in the methods of treatment, and the remarkable contrariety of opinion on the subject of the remedies, are adequate reasons for the formal expression of our views. Obviously, it is our duty to occupy, as well as we may, a judicial position, to weigh the various methods in just proportion, and pronounce a judgment free from any personal bias. Methods of treatment—in the present state of the subject—must be judged from the clinical stand-point. Whilst pathological theories may direct therapeutical efforts, they cannot decide the relative merits of the various plans of treatment. Is there a specific germ? Is the malady first local, or do the local manifestations indicate systemic infection? Such questions must influence the application of remedies; but they cannot decide their value. From either point of view, the treatment of diphtheria must be local and systemic.

The remedies applied to the throat are directed to two ends; to destroy the germs of the disease; to check the spread of the exudation. Both purposes are usually effected at the same time; but not invariably, since some approved remedies have no action on bacteria, especially none on the process of pullulation.

As solvents of the false membrane, we have choice of several. We have the high authority of Mackenzie for regarding lactic acid as the most efficient. As there is no official dilute acid, the pure acid, weakened by the addition of water to the necessary point—about one in three—for dissolving the membrane, is painted over the affected area with a large camel's-hair brush, or is sprayed on. Next to this is lime-water, which may be applied by means of a large mop, or in spray, or, as has been effectively employed, by having the patient breathe the vapor arising from slaking lime. Papaïne, the digestive principle of the *Carica papaya*, has lately been used with striking results as a solvent of diphtheritic false membrane. It appears to be the best of this group of remedial agents, and, as it can have no injurious effect, may be used very freely. Solution of pepsine has also been effectively employed for this purpose.

Many other remedies are used to detach the false membrane. Steam assiduously applied is preferred to all other means by some skilful practitioners. Other agents are solutions of chlorate of potassium, tincture of ferric chloride, and these in combination. Unless the removal by solution, or the mechanical detachment of the membrane, is the preparation for subsequent applications, no practical benefit accrues, except in the case of laryngeal diphtheritis. The membrane removed, the surface beneath is then properly prepared for the action of parasiticides. Many of these are now in use. Sublimed sulphur has appeared to be very beneficial in some cases. Unless some sulphurous acid is formed, the nature of the service rendered by it is by no means clear. The application of sulphur, as, indeed, of all agents in the form of powder, is most conveniently and effectively done by means of an insufflator, which distributes the material uniformly over the surface.

There are several parasiticides of the phenol group which may be very advantageously employed topically. These are carbolic and salicylic acids, resorcin, phenoresorcin, chinolin, and some others. After the detachment of the false membrane, these are applied in solution or in powder to the affected area. A five per cent. solution of carbolic acid can be carefully painted over, or one per cent. solution sprayed on; the former method, when feasible, is to be preferred. Salicylic acid, finely pulverized, and sufficiently diluted, is more effectively used by insufflation, as it adheres more tenaciously, and the action is both more powerful and better sustained. Solutions of the acid, made by aid of biborate of sodium, can also be employed—dashed on by a suitable mop, or more carefully applied with the brush. Resorcin, properly diluted, well dusted on with the insufflator, is also an effective application. The relative utility of these remedies of the phenol group can only be settled by comparative trials.

Another important group of parasiticides, is that composed of iodine, bromine, and mercury com-

pounds. Iodoform has occupied lately a large place in professional confidence, as an antiseptic. In diphtheria it may be used in solution in ether, or, better, in the solid form, finely triturated with some suitable vehicle. The best combination is iodoform and tannin—the latter uniting with the mucus, forming a tough mass which holds the former in contact with the diseased surface. Iodotannin, a compound of iodine and tannic acid, which may be prepared extemporaneously by dissolving tannin in tincture of iodine, is little less effective than iodoform. Dissolved to the proper consistence, the solution can be painted on the affected part, as other fluid applications are made.

Bromine dissolved in water by the aid of potassium bromide, or an alcoholic solution, can be used as are the other members of this group, but it has no special advantages, and is, in respect to several qualities, objectionable.

Mercury is, unquestionably, growing in professional favor as a remedy for diphtheria. Calomel is an efficient topical application, used by the insufflator. When employed in this way, it should be prepared by trituration with sugar of milk, and then thoroughly dusted over the diseased part. Corrosive sublimate is the most destructive parasiticide, but its use requires circumspection. The solution in alcohol—one grain to one ounce of diluted alcohol—is a suitable proportion, but even this must be applied with care, painted or sprayed over the affected parts.

Quinine has, also, been used locally, with apparent advantage. The saturated solution of the hydrochlorate is a good preparation for this purpose. It is best used in the form of spray, which should be frequently and very persistently employed, or by means of a large, soft mop, a quantity of the solution can be dashed on where needed. A solution of quinine made by the aid of hydrobromic acid, may be more desirable, because stronger; but it cannot be used with the same freedom.

Chloral is one of the more useful of the local applications. It has an antiseptic action, is somewhat solvent of false membrane, and, probably, checks its formation. A solution in the proportion of ten grains to the ounce of water, may be applied, as the other solutions above referred to, in the form of spray, or by the brush or mop.

When the diphtheritic process invades the nares, it becomes exceedingly necessary to clear the passage and make efficient antiseptic applications to the diseased membrane. It is even more important in this case than in faucial diphtheria, for the reason that systemic infection is more apt to occur. With a suitable syringe, a solution of lactic acid, or lime-water, or the digestive papaïne, can be used to effect this important purpose. The passage-way opened, carbolic acid, resorcin, salicylic acid, iodized solutions, can be effectively applied. We need hardly assert that both time and patience are required to effect this important object, and unless effected a favorable termination cannot be reasonably hoped for.

The wealth of material at our disposal for the topical treatment of diphtheria is quite equalled by the remedies available for the systemic management. As very considerable depression of the vital powers occurs in every form of diphtheria, properly regulated support is necessary from the beginning. In this disease, as, indeed, in all corresponding maladies, the digestive fluids are wanting in the constituents essential to the process of digestion—pepsin and acid—and, hence, these should be artificially supplied with the foods. Peptonized preparations, *i. e.*, articles of diet partly digested by the addition of pancreatic fluid and an alkali, serve an excellent purpose.

To ply the patient with food which the organs of digestion cannot dispose of, is a not uncommon mistake, responsible, we doubt not, for the vital failure in some cases. Milk, beef-juice, and egg-nog are the most important articles, and with or immediately after them should be uniformly given pepsin and hydrochloric acid, or they should be properly peptonized. As a means of support, and as an important remedy, spirit (whiskey or brandy) plays the chief part in the therapeutical scheme of some practitioners, and by all it is utilized to some extent. That alcohol is, in a limited degree, a food, is now generally conceded; that it is an antiseptic of considerable power, is also recognized on all sides, and that it may be a cardiac stimulant or an antipyretic, according to the quantity administered, is a fact, but one not accepted unreservedly. The function of alcohol in diphtheria will, therefore, be determined by the mode of administration. Rarely, indeed, will the large doses, for an antipyretic effect, be required. Usually, moderate doses, frequently repeated will be administered to procure the effects of an antiseptic and a nutrient. As alcohol precipitates pepsin and destroys its ferment property when present in large quantity, and concentrated, if given to subserve the purpose of a food, it should be administered in small doses, and be freely diluted; if given to act as an antiseptic, it should be administered in large doses, and between the food when the stomach is empty. Any indefinite, especially any hap-hazard prescription of alcoholic stimulant is to be deprecated. The utility of alcohol in diphtheria, rightly given, is certainly great, but on the care with which the administration is conducted depends the degree of usefulness attained.

In our next issue we will consider the systemic treatment.

RESECTION OF THE RIBS FOR CHRONIC EMPYEMA.

In the *Union Médicale*, of January 1 and 29, 1884, may be found a paper by M. Berger, and a discussion at the Société de Chirurgie, on the removal of portions of one or more of the ribs for chronic pyothorax, complicated by a rebellious fistule, with the double object of affording a free outlet for the pent-up fluid and permitting approximation of the walls of the cavity. Of 27 cases, in which the result was known, 10 were completely cured, 8 were greatly relieved, 3 failed, and 6 died, but the deaths, except in one case, could not be attributed to the procedure itself.

The operation is usually described as that of Estlander, who first practised it in 1876, and Berger claims for him the merit of having originated it. Such a statement is, however, utterly unwarranted, as Roser had done the operation in 1865, and Simon repeated it in 1869, and, therefore, preceded Estlander in Europe. The measure in reality originated in this country, on December 8, 1857, with Dr. A. G. Walter, of Pittsburgh, who published a full account of his case in the *British Medical Journal*, of January 21, 1860, from which it appears that portions of the seventh, eighth, and ninth ribs were removed with bone-pliers. Five years later, Dr. Warren Stone, of New Orleans, accomplished the desired objects by excising a disk of the rib with the trephine. It will thus appear that Walter antedated Roser by eight years, and Estlander by nineteen years, and that he is entitled to the credit of having conceived and practised an operation to which the name of another surgeon is commonly attached.

HÆMOGLOBINÆMIA AND HÆMOGLOBINURIA.

Some interesting experiments have recently been made in Germany by Litten and others, consisting in the intravenous injection of substances supposed to have a disorganizing effect upon the red blood-corpuscles, and producing hæmoglobinæmia. Among these were aniline, common salt, and chlorate of potassium.

Litten found, after the injection of aniline, nephritis and an increased quantity of blood-coloring matter in the urine, to which he ascribed the nephritis, and concluded that all substances which dissolve blood-corpuscles act in this manner. Liebreich, on the other hand, ascribed the nephritis to the toxic action of the aniline itself, and not to the hæmoglobin resulting from the disintegration of red corpuscles.

The possibility of the former view is sustained by the results of some experiments by Lassar, who injected the defibrinated blood of an animal into the peritoneal cavity of another of the same species. In the case of rabbits in a few days, and in that of dogs during the second week, a urine of normal hue and without albumen suddenly became highly charged with hæmoglobin, followed by an albuminuria which continued for several months. These conditions were found to be associated with interstitial and sometimes parenchymatous nephritis. The observations of Ponfick and Lebedeff tend to the same conclusion.

The exact import of these results is as yet undetermined, but they have a bearing upon two important pathological conditions. One is that of hæmoglobinuria as we find it resulting from malarial poisoning, and the other is hæmatogenic or blood-icterus, as distinguished from hepatogenic jaundice or that occurring from obstruction of biliary passages and reabsorption of biliary coloring matters.

As to the former, it is well known that it is accompanied by blood-casts and casts made up of the granular débris of red blood-disks; also by hyaline fibrinous casts. We have never considered these as symptomatic of nephritis, but rather due to coagulated blood-elements.

Again, as to blood-icterus, such as occurs in acute yellow atrophy of the liver and other profound dyscrasic conditions. The existence of this is undoubted, and is believed to be due to rapid disintegration of blood-disks and the staining of the tissues by the dissolved hæmoglobin. It would seem, according to Leyden, that this occurs in cases in which the liver and kidney are too quickly involved in the general process to permit them to eliminate the coloring matter separated by these normal channels in health. Such results Leyden claims to have produced by the intravenous injection of potassium chlorate, in which the kidneys are obstructed and the excretion of hæmoglobin interfered with. This explanation seems to us to be a very reasonable one, and argues against the dissolved hæmoglobin being the cause of a nephritis, as claimed by Litten.

GOUTY NEPHRITIS.

In the discussion which took place in the Berlin Medical Society, January 9th, upon Prof. Virchow's paper, referred to in our issue of February 2d, opinion was not in entire accord with the views of the distinguished Professor. Fürstenheim, especially, claimed that in certain cases of stone in the bladder the calculus is made up of the same acicular crystals of urate of sodium which make up gouty tophi, simply grouped in another way—the fluids holding them in solution until they reach the pelvis of the kidney or bladder, instead of depositing them in the tissues, as in gout. Why one situation is selected rather than another, he does

not say, but suggests that a certain property of the cartilages and ligaments may determine the deposition there in given instances.

Fürstenheim argues that the fact mentioned by Virchow, that those suffering with stone seldom or never suffer with attacks of gout, does not prove that both conditions do not result from the same tendency. And further, that as gout is not confined to the rich or free-living, so calculus is also found among the poor.

It is, perhaps, well that attention has been called to this matter by so conspicuous an authority as Virchow, since it is certain that Fürstenheim is not the only practical physician who has heretofore thought that there was a very close relation between uric acid gravel and gout.

COMPULSORY EXPERT TESTIMONY WITHOUT REMUNERATION.

AMONGST the various trials, annoyances, and ills which beset the path of the medical expert, not the least is that against which the Greene County Medical Society of Alabama recently protested—namely, the right of the Commonwealth to demand, without proper compensation, the attendance and professional advice of the expert. Unfortunately, it seems to be well settled that in most of our States the Court has such power, and that the expert has no redress.

The practice is based upon the English law and custom, which are clearly recognized in the last edition of Taylor, as well as in other standard works upon medical jurisprudence. Prof. Washburn, of the Harvard Law School, states the principle in the following language: "If the case be one of a public nature, involving the question of a crime of magnitude, when the public safety requires the investigation, the right to compel the attendance of such a witness becomes an incident to the exercise of government itself, in the same way that a juror is obliged to sacrifice convenience or profit to render a public service."

There is one point which should be generally understood by medical men, namely, that the law applies only to public suits, and that in *private* suits the Court has no power to enforce the presence of the medical witness. In such a suit, according to an English decision in 1843 (1 *Carrington & Kirwein*, 23), a witness called to depose to a "matter of opinion depending on his skill in a particular trade, has, before he is examined, a right to demand from the party calling him a compensation for his loss of time; and there is a distinction between a witness thus called and a witness who is called to depose to facts which he saw."

Without attempting to go over the oft-travelled ground as to the hardships and rights of the medical expert in this matter, we want to call attention to the fact that the *true interests of the Commonwealth* demand that the medico-legal expert, when employed, should be well paid. There is no greater fallacy than that involved in the belief that because a man is a doctor therefore he is qualified to give advice in medico-legal matters. It is essential, in civilized communities, that there be persons who shall give attention to medico-legal questions entirely outside the ordinary duties of the physician. Unless there is a prospect of proper compensation, men of ability will not labor to acquire the knowledge and experience necessary to fit them for special court duty.

The comparison, often made by those advocating the right to gratuitous expert service, should not be between the medical expert and the juryman, but between him and the judge. No special skill or preparation is required of the juryman, whilst expert and judge alike must devote their lives to the study of the subjects coming before them for decision. The State has as much right to claim, without pecuniary return, the time of a military man to lead its armies, of a lawyer to act the part of the judge, or of a business man to manage the State finances, as it has to demand gratuitous service of the medical jurist. The Commonwealth is but an aggregation of units, *i. e.*, citizens, and when this aggregation demands *especial* service, based upon especial skill, the cost should not be poured *en masse* on the single unfortunate unit, *i. e.*, the expert selected by the Court representing the Commonwealth; but should shower in its infinite subdivisions upon all units alike. The doctor paying taxes bears his share of the common expense, which is all that ought to be required of him.

We believe that the only State whose legislature has had the good sense to see that the true interest of the community requires that justice should be done to the medical expert, is Iowa. The Act of 1873 of that State provides that

> "Witnesses called to testify only to an opinion founded on special study or experience in any branch of science, or to make scientific or professional examinations, and to state the results thereof, shall receive additional compensation, to be fixed by the Court, with reference to the value of the time employed and the degree of learning or skill required."

We opine that the Greene County Medical Society has done well in requiring its representatives to urge the Alabama State Society to use its influence in securing similar legislation in Alabama, and express the wish that the matter may be brought forcibly to the attention of all the various State Societies.

A NEW NATIONAL PHARMACOPŒIA.

THE proposition for a National Pharmacopœia appears to meet with general professional commendation, and the only unfavorable criticism which we have seen is based on trivial grounds or on erroneous views of the power of Congress in the premises. Our friends of the *New York Medical Journal*, for instance, seem exercised over the idea that the proposed National Pharmacopœia is to be rendered legally binding on all citizens of the United States by Act of Congress, and it seeks to alarm the pharmaceutical profession with the notion that every druggist who might vary from the directions of such a work would be liable to prosecution. Our contemporary's views as to the constitutional powers of Congress are evidently very hazy, for it adds that "it seems to us that a standard strength and a standard purity are all that the Government can legitimately enforce in the matter of drugs."

If our friends will refer to Article II. Section viii. of the Constitution of the United States, they will find that their fears are groundless, and that their conceptions of the power of Congress are by far too liberal. The authority granted to that body does not extend to fixing a standard of drugs and preparations which shall be imperative on the medical and pharmaceutical professions. It can, however, provide a standard for its own departments, and this is all that Mr. Randall's bill proposes to do. If, as is to be expected, that standard should prove free from the imperfections of the existing Pharmacopœia, the latter would be naturally superseded; but, in any case, it would be for the professions to determine which of the two should be recognized.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 12, 1884.

THE VICE-PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

DISLOCATION OF THE COMMON CAROTID ARTERY.

DR. F. LANGE presented a patient, a woman, forty-seven years of age, who had been troubled with a disagreeable feeling in her throat for about nine months, which she described as a perpetual desire to swallow. She had been treated with internal and external remedies and applications, and called at his office about a week ago, when he examined the throat and discovered what could be readily seen on the posterior wall of the pharynx, on the right side, at the lower edge of the arcus pharyngo-palatinus—a roundish, pulsating tumor. Closer examination showed that it was the common carotid artery, which was dislocated, and could be traced by laryngoscopic examination as far down as the arytenoid cartilage.

There were also hypertrophy of the left ventricle and a decided thickening of the coats of the other carotid artery, which was situated abnormally superficially, and there was some albumen in the urine; and the patient said that about nine years ago she had an attack of acute nephritis. The question was whether the trouble depended upon the anatomical abnormity, and had always existed, or only since the trouble in her throat has been manifested.

On the left side the soft parts are slightly prominent, and are sunk in on the right side. Dr. Lange thought the prominence of the artery on the left side was due to the superficial position of the common carotid artery; moreover, the entire larynx seemed to him to be abnormally movable, especially so as one could pass on the right side the fingers behind the thyroid cartilage and pull the artery out, dislocate it laterally, and push the larynx well over to the opposite or left side. He thought it probable that it was the common carotid and the beginning of the internal carotid which were dislocated. The artery seemed so movable beneath the mucous membrane of the pharynx that, by some pressure from the right side, it would be pushed almost as far as the middle line, passing from there upwards and to the right side in a curved line.

ARTHRITIS DEFORMANS; HYDRARTHROSIS; CORPUS MOBILE; ARTHROTOMY.

DR. LANGE also presented a patient with the following history:

A man, fifty-eight years of age, has been troubled with his right knee for a good many years, and attributes it to a very curious cause, namely, for more than fifteen years he has suffered from a constant feeling of pressure in the region of the rectum, which obliged him to use the chamber-pot very frequently. By and by he fell into the bad custom of so frequently yielding to this sensation that he must have been seated the greater part of the day on a small pot which he used to carry with him. The most thorough examination does not reveal any material change in or about the rectum which might explain this suffering, and I think it to be a symptom of marked hypochondriasis, which of late, through mere exercise of will, has been markedly improved. Now the patient himself thinks that this constant low sitting posture, with much flexed knees—and more so the right one—was a great strain to the latter. By and by it became thickened and abnormally movable; though he could walk, he was unable to use it for lengthy exercise. When I saw the patient in August, last year, his right knee presented, in fact, a grotesque appearance. It was the largest knee-joint I ever saw, except one, and its circumference was twenty centimetres more than that of the healthy side, which was due mostly to fluid within the capsule. The latter seemed much thickened, and so distended, that the upper recess almost reached the middle length of the femur. There existed in the popliteal space a protuberance of the size of about a medium-sized fist, having itself a smaller protuberance the size of a small apple, resistant and smooth, and located behind and above the external condyle. The leg was somewhat œdematous; subcutaneous veins distended. Flexion and extension could be made almost to the normal boundaries. Besides, there existed lateral mobility to such a degree that at each step the knee was

markedly projected outwards, and a strong genu valgum set in. You will see this abnormity still present if the patient removes his apparatus.

Performed arthrotomy in September last by two long, lateral incisions. A large amount of synovial fluid escaped, and such an enormous mass of soft, fibrinous layers that I do not think the latter were less than a pint. They were mostly scraped out by means of a sharp spoon, leaving the synovial membrane thickened, smooth, velvet-like, and highly vascularized. Together with those masses this long body escaped, about the size of a large bean, rough surface, bony, but covered with a very thin layer of cartilage, as you see on the cross-cut. The bony parts and cartilage of the joint presented the characteristic changes of arthritis deformans. Impressions and elevations on the cartilages. The edges of the bone thickened and broadened by irregular pad-like protuberances. The swelling in the popliteal region was hardly affected by the incisions in front, and became only a little smaller. I should have incised also, but contrary to my expectation the patient had lost a great deal of blood, mostly from the highly vascularized and thickened synovial membrane, so that I was obliged to desist for the present from further surgical interference. Drains were inserted, the wounds closed by suture, and the knee immobilized, of course, above an antiseptic dressing. For the first days the discharge of a synovial-like fluid was so ample that the dressing had to be changed almost daily, but healing took place without bad symptoms within about four weeks. The size of the knee has been considerably reduced —according to a measurement two months after the operation, by about thirteen centimetres; at present it is forty-two centimetres, which means twelve centimetres less than at the time of the operation. The swelling in the popliteal space is also decidedly smaller and softer, and you feel in it, here and there, on motion a soft crepitus, as if fibrinous bodies escape under the pressure of the finger. The abnormal lateral mobility has not been improved so far. I have the patient wearing this very solid and strong, double-iron splint from the pelvis to the knee. A counter-pressure is, at the same time, exerted upon the outside of the leg, immediately below the knee, to counteract the tendency toward outward subluxation of the tibia. It seems as if there is some loss of bony substance at the inner condyles, so that a wide gap is formed between them if you force the leg in a straight position. My idea is to maintain this position by the splint, thereby causing pressure of the external condyles against each other and gradual loss of bony substance until both surfaces can meet again to such an extent that the adaptation is perfect. Perhaps complete anchylosis would be the most favorable result to the patient.

Neither any abnormity of sensibility nor of function of the sphincters exists, which might entitle us to assume a spinal origin of the affection.

ADDUCTION AND ABDUCTION IN FRACTURES OF THE NECK OF THE FEMUR.

DR. W. S. HALSTED presented a case of fracture of the neck of the femur with abduction, and a specimen of intracapsular fracture of the neck of the femur from a case in which there had been adduction and one-eighth of an inch lengthening.

He called attention to the necessity of making allowance for adduction and abduction in the estimation of the amount of shortening in these cases. From certain measurements made upon dead and living subjects, he had demonstrated that as abducting the lower limb makes it measure less along the line from the anterior superior spine of the ilium to either malleolus, so adducting it makes it measure more along the same line. Furthermore, that one leg being adducted, the other must be abducted to be brought parallel with it. Hence, in fractures of the neck of the femur with adduction the injured limb might actually measure longer than the sound one; first, because it is lengthened by adduction, and, second, because its fellow is shortened by abduction.

In the case from which the specimen was taken he was enabled to make the diagnosis of fracture because of a recognition of these facts. The injured limb was *apparently* shortened, but by measurement, from anterior superior spine of ilium to malleolus, it was lengthened one-eighth of an inch, although one-fourth of an inch shortened along Bryant's line.

The patient presented with fracture of the neck of the femur and abduction had limbs of apparently equal length. Along Bryant's line the injured limb measured three-eighths of an inch, but from anterior superior spine of ilium, one-eighth, and from the malleolus externus, one and one-fourth inch shorter than the sound one. Dr. Halsted remarked further, that of cases which, measured on Bryant's line, were equally shortened, the adducted limbs would necessitate more of a limp than the abducted ones. In consideration thereof he believed it unwise to allow the limb to remain in an adducted position.

DR. POST remarked with regard to the anatomical specimen, that it would hardly seem probable that such a degree of absorption could have taken place within two weeks unless there had been some previous disease. The specimen itself would seem to indicate that several months must have passed after the receipt of the injury.

DR. HALSTED said the man certified that he had never had any trouble with his hip-joint, and had never been obliged to walk with a limp nor had he received any injury.

ANEURISM OF THE FEMORAL ARTERY; LIGATION OF THE EXTERNAL ILIAC; CURE.

DR. MCBURNEY presented a patient with the following history: A man, fifty-seven years of age, ten years ago received a slight injury over the right femoral artery, high up, and apparently in consequence of that a tumor formed, which has slowly but steadily increased in size, when, at the end of that time he came under Dr. McBurney's observation. The patient had not had any pain or inconvenience from the tumor, but on account of its rapidly increasing growth of late, he sought advice, and in November last came under Dr. McBurney's care, who found a pulsating tumor in Scarpa's triangle, which presented the usual phenomena of an aneurism.

Dr. McBurney advised digital compression, but the patient was not prepared at that time to submit to treatment, and returned to his home in Vermont. After doing considerable hard work, he returned in December, and when Dr. McBurney then saw him he found Scarpa's triangle almost entirely occupied by the tumor, which

also extended outward as far as the external edge of the great trochanter. It pulsated throughout its entire extent. He thought there still was room above the tumor to apply digital compression, which method was faithfully applied continuously for twelve hours by Dr. Woodward and other members of the House Staff, but without avail. He then—on December 20th—ligated the external iliac artery. The operation was performed in the usual way. One noticeable feature about it was that the vessel was so tortuous that it descended below the pelvis as much as an inch and a half, and had to be drawn up in order to throw a ligature about it. The operation was performed under frequent irrigations of bichloride solution, and catgut was used, which was applied about two inches above Poupart's ligament. The gut was an "E" violin string, prepared and given to him by Dr. Briddon. The iodoform-gauze dressing was applied, and the first dressing was allowed to remain six days; at the end of that time it was removed, and the wound was found entirely healed except where the drainage-tube had been inserted. A new dressing was applied, which was removed four or five days afterward, and the subsequent progress of the case was favorable and entirely uninterrupted. Nothing occurred after the operation in the way of interference with the circulation, such as sometimes manifests itself in cutaneous lesions. Dr. McBurney had not been able to find any pulsation or bruit in the tumor since the operation. It had diminished in size somewhat, but just how much he was at the time unable to say. It was nearly eight weeks since the operation was performed, and it seemed to him to be a satisfactory cure.

DR. E. L. KEYES then read a paper on

THE GEOGRAPHICAL DISTRIBUTION OF URINARY CALCULUS, WITH AN INQUIRY INTO ITS CAUSE.

(See page 233.)

Dr. POST said that he had lately received a letter from his son in Beyrout, Syria, in which he stated he had just performed his twenty-first operation for stone, showing that stone is very prevalent in that region, including Syria and the adjacent provinces. All these operations have been performed within fourteen years. There are other operators in that locality, but most of the operations had been performed by Dr. Post, and probably also chiefly in hospital service. The climate is a semi-tropical one.

DR. LANGE exhibited an

ARRANGEMENT FOR HOLDING NEEDLES AND SILK,

which might recommend itself for very fine needles which are used for suture of the intestine, it being rather tedious to arm the needles during the operation. Thread the needles, secure them between two rubber bands of disinfected drainage-tube around an ordinary test-tube, also secure the ends of the silk around the other extremity with another rubber band, and immerse the whole in an ordinary lamp chimney filled with glycerine, and cork with rubber corks. Thus far the needles had not corroded when kept in pure American glycerine, nor had he noticed that the sulphur which the rubber mostly contains had tarnished them.

COMPOUND DISLOCATION OF THE FIRST PHALANX OF THE GREAT TOE.

DR. J. C. HUTCHISON was called to see a man who had fallen from a tight-rope. He visited the patient within half an hour after the accident, and found that he had a compound dislocation, backwards, of the first phalanx of the great toe. The wound was on the inner side, communicated with the joint, and was about half an inch in diameter. All the usual expedients were resorted to for effecting reduction, but without accomplishing it. He then divided the internal lateral ligament, a portion of which seemed to have been torn. Subsequently he divided the external lateral ligament, and still was unable to reduce the dislocation. He then divided, subcutaneously, the tendon of the extensor proprius pollicis, and at once was able to put the bone into position. No splint was used; the toe was simply enveloped with a considerable quantity of cotton-wool, and surrounded with a bandage. At the end of three or four days, the dressing was removed and reapplied. Dr. Hutchison saw the patient walking with a crutch about a week after the occurrence of the accident, and learned that he had a satisfactory recovery. The case was interesting to him, because it was the only one he had ever met with, and it was also one which illustrated the same difficulty of reduction that is observed in dislocations of the thumb.

DR. MCBURNEY asked if the extensor tendon of the toe seemed to be the resisting point.

DR. HUTCHISON said it seemed so, and he had an impression that if he had divided this tendon first, reduction could have been effected without further operative interference.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, February 6, 1884.

THE PRESIDENT, SAMUEL LEWIS, M.D., IN THE CHAIR.

DR. H. C. WOOD read a paper on the

CLINICAL ASPECTS OF CEREBRAL SYPHILIS.

He said that it is naturally to be expected that any cause of ordinary brain inflammation would, when present in a syphilitic person, tend to precipitate a specific cerebral disease. Thus, as thermic fever frequently provokes chronic meningitis, much plausibility attaches to the report of a case in the *Journ. de Méd. et Chir. prat.*, Paris, 1879, p. 291, in which the cerebral syphilis is ascribed to a sunstroke. Blows and other traumatisms would, in a similar manner, be supposed to figure largely as exciting causes of brain syphilis; but he has never met with a case having such relations, and reports of them are rare in literature.

Various authorities attach much influence to overstudy and other forms of cerebral strain in exciting brain syphilis, but neither in private nor public practice has he met with any instance where over-brain work could be considered a distinct etiological factor, and cases of brain syphilis in which any exciting cause can be found are very rare.

The inherited diathesis is less prone to manifest itself in the nervous system than in other portions of the body, but it certainly is capable of causing every type of nervous disease that follows infection from impure coition.

It is a matter of great interest to know how late in life nervous disease from inherited taint may develop.

We have, as yet, little light upon the equally interesting and cognate problem as to how far inherited syphilis may produce late in life nervous diseases whose type is not distinctly specific, but it is probable that even after puberty specific nervous affections may appear for the first time in the unfortunate offspring of syphilitic parents.

Some time since, Dr. Wood saw, in an orphan of fourteen, a chronic basal meningitis, and, in the absence of any history, gave the fatal prognosis of tubercular disease; but to his astonishment, under the long-continued use of iodide of potassium, complete recovery occurred. No signs of inherited syphilis were perceptible, but the specific nature of the inflammation is, in view of the result, scarcely doubtful. It is probable that in some of the reported cases of recovery from alleged tubercular meningitis, the affection has been really syphilitic.

Nervous diseases following acquired syphilitic infection certainly belong to the advanced stages of the disorder. From the third to the tenth year may be considered the period of maximum frequency of nerve accidents.

The fact that cerebral syphilis may occur many years after the cessation of all evidence of the diathesis is one of great practical importance, especially when taken in conjunction with the circumstance that the nervous system is more prone to be attacked when the secondaries have been very light than when the earlier manifestations have been severe. I have repeatedly seen nervous syphilis in persons whose secondaries have been so slight as to have been entirely overlooked or forgotten, and who honestly asserted that they never had had syphilis, although they acknowledged to gonorrhœa or to repeated exposure, and confessed that their asserted exemption was due to good fortune rather than chastity.

Although syphilis is most prone to attack the nervous system many years after infection, it would be a fatal mistake to suppose that brain disease may not rapidly follow the occurrence of a chancre. The minimum possible intermediate period is certainly very brief.

In a case which recently occurred in the practice of Dr. A. Sydney Roberts, of this city, the chancre appeared after a period of incubation of twenty-six days, and two months and eight days subsequent to this came the first fit; eight days after the first the second convulsion occurred, with a distinct aura, which preceded by some minutes the unconsciousness.

The recorded cases show that cerebral syphilis occurs not very rarely within six months after infection, and may be present in two months.

An interesting observation in this connection is that of Dr. Ern. Gaucher (*Revue de Méd.*, 1882, ii. 678) of a spinal syphilis occurring six months after the appearance of a chancre.

Disease of Brain Membranes.—Specific affections of the brain membranes very often declare themselves with great suddenness. The records of the disease present case after case in which an apoplectic attack, a convulsive paroxysm, a violent mania, or a paralytic stroke, has been the first detected evidence of syphilitic cerebral disease. On the other hand, in many instances the symptoms come on slowly and successively.

Headache, slight failure of memory, unwonted slowness of speech, general lassitude, and especially lack of willingness to mental exertion, sleeplessness or excessive somnolence, attacks of momentary giddiness, vertiginous feelings when straining at stool, yelling, or in any way disturbing the cerebral circulation, alteration of disposition—any of these, and *à fortiori*, several of them, occurring in a syphilitic subject, should be the immediate signal of alarm, and lead to the examination of the optic disks. Of course, if choked disk be found, the diagnosis becomes practically fixed, but the absence of choked disk is no proof that the patient is not suffering from cerebral syphilis. There is one symptom that may occur during the prodromic stage, and which, in a person not hysterical, should give rise to the strongest suspicion: this is repeated, partial, passing palsies. A momentary weakness of one arm, a slight drawing of the face disappearing in a few hours, a temporary dragging of the toe, a partial aphasia which appears and disappears, a squint which to-morrow leaves no trace, may be due to a non-specific brain tumor, to miliary cerebral aneurisms, or to some other non-specific affection: but in the great majority of cases where such phenomena occur repeatedly, the patient is suffering from syphilis or hysteria.

It is doubtful whether an acute syphilitic meningitis can ever develop as a primary lesion; whether it must not always be preceded by a chronic meningitis or by the formation of a gummatous tumor; but it is very certain that acute meningitis may develop when there have been no apparent symptoms, and may, therefore, seem to be abrupt in its onset.

Some years ago I saw, in consultation, a man who, in the midst of apparent health, was attacked by violent meningeal convulsions, with distinct evidences of acute meningitis. He was apparently saved from death by very heroic venesection, but after his return to consciousness developed very rapidly a partial hemiplegia, showing that a latent gumma had probably preceded the acute attack. On the other hand, an acute attack is liable at any time to supervene upon a chronic syphilitic meningitis. At the University Hospital Dispensary, I once diagnosed chronic cerebral syphilis in a patient who the next day was seized with violent delirium, with convulsions and typical evidences of acute meningitis, and died four or five days afterwards. At the autopsy an acute meningitis was found to have been engrafted on a chronic specific lesion of a similar character.

In the cases of *chronic meningeal syphilis* which have come under my observation, most usually after a greater or less continuance of prodromes, such as have been mentioned, epileptic attacks have occurred with a hemiplegia, or a monoplegia, which is almost invariably incomplete and usually progressive; very frequently diplopia, from palsy of the ocular muscles, is manifested before the epilepsy. Not rarely oculo-motor palsy is an early and pronounced symptom, and a marked paralytic squint is very common. Along with the development of these symptoms, there is almost always distinct failure of the general health, and progressive intellectual deterioration, as shown by loss of memory, failure of the power to fix the attention, mental bewilderment, and, perhaps, aphasia. If the case convalesce under treatment, the amelioration is gradual, the patient travelling slowly up the road he has come down. If the case end fatally, it is usually by a gradual sinking into complete nerve-paralysis, or the patient is carried off by an acute inflammatory exacerbation, or, as I saw in one case, amelioration may be rapidly occurring, and a very

violent epileptic fit produce a sudden asphyxia. In this form of cerebral syphilis, death from brain-softening around the tumor is not infrequent; but a fatal apoplectic hemorrhage is rare.

The clinical varieties of cerebral meningeal syphilis are so polymorphic and kaleidoscopic that it is almost impossible to reduce them to order for descriptive purposes. Heubner makes the following types:

"1. Psychical disturbances, with epilepsy, incomplete paralysis (seldom of the cranial nerves), and a final comatose condition usually of short duration.

"2. Genuine apoplectic attacks with succeeding hemiplegia, in connection with peculiar somnolent conditions, occurring in often-repeated episodes; frequently phenomena of unilateral irritation, and generally at the same time paralyses of the cerebral nerves.

"3. Course of the cerebral disease similar to paralytica dementia."

In regard to these types, the latter seems clear and well defined, but contains those cases which will be discussed under the head of cortical disease.

Meningeal syphilis, as seen in this country, does not conform rigidly with the other asserted types, although there is this much of agreement, that when the epilepsy is pronounced, the basal cranial nerves are not usually paralyzed, the reason of this being that epilepsy is especially produced when the gummatous change is in the ventricles or on the upper cortex. In basal affections, the epileptoid spells, if they occur at all, are usually of the form of petit mal; but this rule is general, not absolute. The apoplectic somnolent form of cerebral syphilis, for some reason, is rare in this city; and it seems necessary to add to those of Prof. Heubner's, a fourth type to which a large proportion of our cases conform. This type I would characterize as follows:

4. Psychical disturbance without complete epileptic convulsions, associated with palsy of the basal nerves, and often with partial hemiplegia.

Headache is the most constant, and usually the earliest symptom of meningeal syphilis; but it may be absent, especially when the lesion is located in the reflexions of the meninges, which dip into the ventricles, or when the basal gumma is small and not surrounded with much inflammation. That it may continue for years without the development of other distinct symptoms is remarkable. It sometimes disappears when other manifestations develop. It is—except in very rare cases—at least so far paroxysmal as to be subject to pronounced exacerbations. In most instances it is entirely paroxysmal, and these paroxysms may occur only at long intervals. Such distant paroxysms are usually very severe, and are often accompanied by dizziness, sick stomach, partial unconsciousness, or even by more marked congestive symptoms. The pain may seem to fill the whole cranium, may be located in a cerebral region, or fixed in a very limited spot. According to my own experience, any localized soreness indicates an affection of the bone or of its periosteum.

There is nothing absolutely characteristic in this headache; but excessive persistency, apparent causelessness, and a tendency to nocturnal exacerbation, should in any cephalalgia excite suspicion of a specific origin—a suspicion which is always to be increased by the occurrence of slight spells of giddiness, or by delirious mental wandering accompanying the paroxysms of pain.

Disorders of Sleep.—There are two antagonistic disorders of sleep, either of which may occur in cerebral syphilis. Insomnia is more apt to be troublesome in the prodromic than in the later stages, and is not of itself of much significance. Somnolence may occur in non-specific lepto-meningitis, and in states of altered brain nutrition from senile or other degenerations of the walls of the cerebral vessels, and is therefore not pathognomonic of cerebral syphilis, yet of all the single phenomena of the latter disease it is the most characteristic.

As I have seen it, it occurs in two forms: In the one variety, the patient sits all day long or lies in bed in a state of semi-stupor, indifferent to everything, but capable of being aroused, answering questions slowly, imperfectly, and without complaint, but in an instant dropping off again into his quietude. In the other variety, the sufferer may still be able to work, but often falls asleep while at his tasks, and especially towards evening has an irresistible desire to slumber, which leads him to pass, it may be, half of his time in sleep. This state of partial sleep may precede that of the more continuous stupor, or may pass off when an attack of hemiplegia seems to divert the symptoms. The mental phenomena in the more severe cases of somnolency are peculiar. The patient can be aroused; indeed, in many instances he exists in a state of torpor rather than of sleep; when stirred up, he thinks with extreme slowness, and may appear to have a form of aphasia; yet, at intervals, he may be endowed with a peculiar automatic activity, especially at night. Getting out of bed; wandering aimlessly and seemingly without knowledge of where he is and unable to find his own bed; passing his excretions in a corner of the room, or in other similar place, not because he is unable to control his bladder and bowels, but because he believes that he is in a proper place for such act—he seems a restless automaton rather than a man.

Apathy and indifference are the characteristics of this state, and yet the patient will sometimes show excessive irritability when aroused, and will at other periods complain bitterly of pain in his head, or will groan as though suffering severely in the midst of his stupor, at a time, too, when he is not able to recognize the seat of the pain. This somnolent condition may last many weeks.

In its excessive development, syphilitic stupor puts on the symptoms of advanced brain softening, to which it is, indeed, often due. Nevertheless, a prolonged deep stupor in persons suffering from cerebral syphilis does not prove the existence of extensive brain softening, and is not incompatible with complete recovery.

Paralysis.—A specific palsy may be of any conceivable variety, and affect either the sensory, motor, or intellectual sphere. The mode of onset is as various as the character of the palsy. The attack may be instantaneous, sudden, or gradual. It will be usually noted that the palsy is incomplete; in rare instances it may be at its worst when the patient awakes from an apoplectic seizure, but mostly it progressively increases for a few hours, and then becomes stationary.

A suddenly developed *complete* hemiplegia, or other paralysis, may be considered as in all probability either hemorrhagic or produced by a thrombus so large that the results will be disorganization of the brain substance, and a future no more hopeful than that of a clot. On the other hand, an *incomplete* palsy may be rationally

believed to be due to pressure or other removable cause, and this belief is much strengthened by a gradual development.

Morbid exudations, not tubercular nor syphilitic, are very rare at the base of the brain. Hence a rapidly, but not abruptly, appearing strabismus, ptosis, dilated pupil, or any paralytic eye symptom in the adult is usually of syphilitic nature.

Motor palsies are more frequent than sensory affections in syphilis, but hemianæsthesia, localized anæsthetic tracts, indeed any form of sensory paralysis may occur. Numbness, formications, all varieties of parasthesia are frequently felt in the face, body, or extremities. Violent peripheral neuralgic pains are rare, and generally when present denote neuritis.

The special senses are liable to suffer from the invasion of their territories by cerebral syphilis, and the resulting palsies follow courses and have clinical histories parallel to those of the motor sphere. The onset may be sudden, or gradual, the result temporary or permanent. Like other syphilitic palsies, paralyses of special senses may come on suddenly or gradually, and may occur paroxysmally.

Aphasia is usually a symptom of advanced disease, but may be a primary evidence of cerebral syphilis.

Coming on after an apoplectic or epileptic fit, it may be complete or incomplete: owing to the smallness of the centre involved, and the ease with which its function is held in abeyance, a total loss of word-thought is not so decisive as to the existence of cerebral hemorrhage as is a total motor palsy. Like hemiplegia or monoplegia, specific aphasia is sometimes transitory and paroxysmal.

Owing to the centres of speech being situated in the cortical portion of the brain, aphasia in cerebral syphilis is very frequently associated with epilepsy. Of course, right-sided palsy and aphasia are united in syphilitic as in other disorders. If, however, the statistics given by M. Tanowsky (*L'Aphasie Syphilitique*) be reliable, syphilitic aphasia is associated with left-sided hemiplegia in a most extraordinarily large proportion. This concurrence of left-sided paralysis and aphasia probably depends partly upon the great frequency of multiple brain lesions in syphilis, and partly upon the habitual involvement of large territories of the gray matter secondarily to diseased membrane. The conjoint existence of left hemiplegia and aphasia is almost diagnostic of cerebral syphilis.

Amongst the palsies may be considered the disturbances of the renal functions which are met with in cerebral syphilis, and which are probably usually dependent upon the specific exudation pressing upon the vaso-motor centres in the medulla. Fournier speaks of having notes of six cases in which polyuria and polydipsia were present. Servantié reports true saccharine diabetes, and I have seen one such case.

Epilepsy.—Epileptic attacks are a very common symptom of meningeal syphilis, and are of great diagnostic value. The occurrence in an adult of an epileptic attack, or of an apoplectic fit, or of a hemiplegia after a history of intense and protracted headache, should always excite grave suspicion.

Syphilitic epilepsy may occur either in the form of petit mal or of the haut mal, and in either case may take on the exact characters and sequence of phenomena which belong to the so-called idiopathic or essential epilepsy. The momentary loss of consciousness of petit mal will usually, however, be found to be associated with attacks in which, although voluntary power is suspended, memory recalls what has happened during the paroxysm; attacks, therefore, which simulate those of hysteria, and may lead to an error of diagnosis.

In many cases of specific convulsions, the movements are in the onset—or, more rarely, throughout the paroxysm—unilateral. This restriction of the convulsion simply indicates that the fit is due to a cortical organic lesion of some kind.

A specific epilepsy may be replaced by a local spasm. Thus, in one of my cases, the repeated epileptic convulsions ended in a painless tic. The clonic spasms were very frequent and violent, and mostly confined to the left facial nerve. The trigeminus was never affected, but in the severer paroxysms the left hypoglossal and spinal accessory nerves were profoundly implicated in all of their branches. Once, fatal asphyxia from recurrent laryngeal spasm was apparently averted only by the free inhalation of the nitrite of amyl.

Psychical Symptoms.—As already stated, apathy, somnolence, loss of memory, and general mental failure are the most frequent and characteristic mental symptoms of meningeal syphilis; but, as will be shown further on, syphilis is able to produce almost any form of insanity, and therefore mania, melancholia, erotic mania, delirium of grandeur, etc., may develop along with the ordinary manifestations of cerebral syphilis, or may come on during an attack which has hitherto produced only the usual symptoms.

That the attacks of syphilitic insanity, like the palsies of syphilis, may at times be temporary and fugitive, is shown by a curious case reported by D. H. Hayes Newington (*Journ. Ment. Sci.*, London, xix. 555), in which, along with headache, failure of memory, and ptosis in a syphilitic person, there was a brief paroxysm of noisy insanity.

Diseases of Brain Substance.—Very few alienists recognize the existence of a distinct affection entitled to be called syphilitic insanity, and there are some who deny that insanity is ever directly caused by syphilis. It is certain that syphilis is often an indirect cause of an insanity which could not be properly styled syphilitic; but if there be disease of the brain cortex produced directly by syphilis, of course such disease must give rise to mental disorders, and, if the lesion be situated in such a way as to affect the psychic and avoid the motor regions of the brain, it will produce mental disorder without paralysis, *i. e.*, a true insanity: again, if such brain disease be wide-spread, involving the whole cortex, it will cause a progressive mental disorder resembling the so-called general paralysis of the insane, or dementia paralytica.

As a man having syphilis may have a disease which is not directly due to the syphilis, when a syphilitic person has any disorder, there is only one positive way of determining how far said disorder is specific, namely, by studying its amenability to anti-syphilitic treatment. In approaching the question whether a lesion found after death is specific or not, of course such a therapeutic test as that just given is inapplicable. We can only study as to the coexistence of the lesion in consideration with other lesions known to be specific. Such coexistence of

course does not absolutely prove the specific nature of a nutritive change, but renders such nature exceedingly probable.

What has just been said foreshadows the method in which the subject in hand is to be here examined, and the present chapter naturally divides itself into two sections: the first considering the coexistence of anatomical alterations occurring in the cerebral substance with syphilitic affections of the brain membranes or blood-vessels, the second being a clinical study of syphilitic insanity.

Medical literature contains a sufficient number of cases[1] in which cerebral sclerosis was found after death to coexist with undoubted specific lesions of the brain membranes and other parts of the body, to demonstrate that sclerosis of the brain substance not only may coexist with a brain lesion which is certainly specific in its character, but may also present the appearance of having developed *pari passu* with that lesion, and from the same cause.

Cerebral meningeal syphilis may coexist with various forms of insanity; and it is probable that in some of these cases there has been that double lesion of membrane and gray brain-matter; further, if there is a syphilitic insanity, which exists without evidences of meningeal syphilis, and is capable of being cured by anti-specific treatment, such insanity must be considered as representing the disease of the gray matter of the brain.

[An analysis of twenty-three cases of this character was then given by Dr. Wood, but is here omitted for want of space.—Ed.]

Of all the forms of insanity, general paralysis is most closely and frequently simulated by specific brain disease. The exact relation of the diathesis to true, incurable, general paralysis, it is very difficult to determine. It seems well established that amongst persons suffering from this disorder, the proportion of syphilitics is not only much larger than normal, but also much larger than in other forms of insanity.

Those who suffer from syphilis are exposed in much greater proportion than are other persons to the indirect causes of general paralysis: but I think we must recognize as established, the opinion of Voisin that there is a syphilitic periencephalitis which presents symptoms closely resembling those of general paralysis. Such cases are examples of the pseudo-paralysie générale of Fournier.

The question as to the diagnosis of these cases from the true incurable paresis is, of course, very important.

The points which have been relied upon as diagnostic of syphilitic pseudo-general paralysis are:

The occurrence of headache, worse at night and present amongst the prodromes.

An early persistent insomnia, or somnolence; early epileptiform attacks.

The exaltation being less marked, less persistent, and perhaps less associated with general maniacal restlessness and excitement.

The articulation being paralytic rather than paretic.

The absence of tremulousness; especially of the upper lip (Fournier).

The effect of anti-specific remedies.

[1] Analyses of a number of these cases were given.

The absence, however, of these marks of specific disease is not proof that the patient is not suffering from syphilis.

I have seen symptoms of general paralysis occurring in persons with a specific history, in which, of these so-called diagnostic differences, the therapeutic test was the only one that revealed the true nature of the disorder. In these persons a primary, immediate diagnosis was simply impossible.

In conclusion, I consider, as proved, that syphilis may produce a *disorder whose symptoms and lesions do not differ from those of general paralysis; that true general paralysis is very frequent in the syphilitic; that the only perceptible difference is one of curability; that the curable sclerosis may change into or be followed by the incurable form of the disease.*

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 21, 1884.

The President, Fordyce Barker, M.D., LL.D., in the Chair.

Dr. John C. Dalton, President of the College of Physicians and Surgeons, read a paper on

THE DIFFERENCES IN FORM OF THE ADULT HEAD.

A short time ago, he said, he had been interested in a new method of comparing the differences met with in the adult human head, viz., by means of the paper patterns employed by hatters. By the use of the well-known brass apparatus employed by them to take the outline of the head at the level at which the hat was worn, a diagram of the shape of the head, on a diminished scale, and marked out by a series of perforations, was secured. This was then transferred to another machine, by means of which two and one-eighth inches were added on all sides, and the outer circle of upright rods constituted the mould upon which the hat was fitted. A great variety of outlines of heads could thus be made, and he had secured three hundred and sixty of them from one shop in New York. Dr. Dalton then had passed around the room a couple of frames, in which were exhibited a number of paper patterns, exhibiting the most striking differences and variations; explaining that these were somewhat exaggerated in length as compared to breadth, on account of the fact that in the reduced diagrams two and one-half inches were taken off all around, and this would have the effect mentioned.

In regard to the general shape of human heads there were two great classes, the long and the round. A medium head would be represented by the figure 125 for the length and 100 for the width. Taking 100 for the standard of width, all between 120 and 130 in length were medium heads, all above 130 long heads, and all below 120, round heads. Different heads varied greatly in regard to the relative width of the back and front parts, in regard to being curvilinear throughout or presenting some angles and straight lines, and in the symmetrical or asymmetrical character of the two sides. To illustrate these points, Dr. Dalton exhibited a series of eight paper patterns, representing the exact size and outlines of eight different heads. The first was regular

in shape, presenting a curvilinear and comparatively symmetrical oval, which resembled in its general outline that of an egg, with the larger end behind, and the smaller in front. The second presented a squaring of the front part of the head; the temples being decidedly flattened. In many individuals there was actually a hollowing out of the temples, and difficulty was consequently met with in securing a well-fitting hat. In the third, the square front was still visible, but the occiput was not rounded, as in the other two, being somewhat elongated. Consequently the long head was beginning to appear, instead of the medium, and in this instance the length was 135. In the fourth, the extreme of elongation was reached, so far as had been met with by Dr. Dalton, the length being 153. In the fifth, however, there was a round head, which was literally symmetrical, and having the proportion of the length as to the breadth of 108 to 100. In the sixth, the length was 117, and here the occiput was seen to be wider and the front part of the head narrower than in the others. No. 7 was remarkable as being the most unsymmetrical of all; and in No. 8, the length was 128, while there was a broad occiput.

One of the most prominent features in almost all of them was the want of symmetry. This was not always apparent at a distance, but if the paper pattern of the head was doubled, the difference between the two sides could at once be seen. When this test was applied to them all in turn, No. 6 was found to be the most nearly symmetrical. No. 7 was found to overlap towards the front on one side and towards the rear on the other. Want of symmetry, then, was the rule, and Dr. Dalton said he had never yet seen an absolutely symmetrical head. The same thing was true also of the brain, and this fact was one of the first things that would strike anyone engaged in making sections of the organ. If the attempt were made to pass a knife down in the median line, between the two hemispheres, the convolutions of the opposite sides would be found often to overlap, while the cerebellum would be more or less twisted as regards the cerebrum; so that it would be impossible to make a symmetrical section. Again, if a series of vertical sections were made with the utmost care from before backward, it would always be found that one lateral ventricle was opened before the other. All this was not surprising, however, when it was remembered that no face was symmetrical. The student was, therefore, liable to be somewhat misled by the plates and drawings which he was accustomed to see, which always represented the two sides of the brain as perfectly symmetrical.

There were one or two matters of interest connected with this subject, Dr. Dalton went on to say, and one was the fact that these diversities in symmetry were always in one direction. There was to be noted, as a rule, a decided preponderance towards one side, and consequently an apparent twisting of the head in that direction. Thus, if the occiput were flattened on one side, it would be found that the temple would be flattened on the other. In several cases a twist towards the left side was marked, and out of twelve instances in which the head was perceptibly twisted, in nine the obliquity was towards the left, and in only three towards the right. This inclination to the left, therefore, seemed to be marked in the crania met with in New York. Whether the same would hold true of the heads of persons living in other parts of the world, he was unable to say. A similar remark would apply to the relative proportion of the long and short axes of the head. In New York there was a decided preponderance of the long head. He had found that 64 per cent. of the heads studied were medium, or with a long diameter between 120 and 130. Below 120 there were 10 per cent., and above 130 26 per cent.; so that the long heads outnumbered the round ones in the ratio of at least 2½ to 1. In other countries the results might, of course, be different.

These differences between the two sides of the same head and between different heads are of interest, again, in connection with the hypothesis which was now very generally accepted, that all parts of the brain did not have the same functions. The doctrine of cerebral localization recognized that the gray matter in some parts of the brain performed different nervous actions from that in other parts. There are, thus, motor centres and perceptive centres, and it was believed that this difference in function was connected with a difference of structure; the cells of the motor tract, for instance, being different from those of any other part in character and arrangement. From the external examination of a long head it might very naturally be supposed that there was a larger quantity of gray matter in the cerebral substance than in a round one, because a long one presented a surface of greater extent than a short one. This might, indeed, be true if the external surface of the brain was smooth. On the contrary, however, we know that the cortical layer of brain tissue was not smooth, but convoluted; and in the brain contained within a round head the fissures might be deeper, and the foldings more numerous and complex than in one belonging to a long head. The shape also varied in other ways, as in the length of the vertical diameter, and, therefore, we could not conclude that because a head was round and compact, the brain contained less gray matter than a long one.

There was still another consideration of even greater importance. The motor centres might be precisely the same in structure, while the fissures might be either deep and narrow, or shallow and broad; so that there might be exactly the same amount of gray matter in two brains which were of very different form. These points were worthy of consideration, he thought, when it was remembered that differences in form might be due purely to external causes. In certain tribes of Indians it was well known that the heads of the papooses were artificially compressed in certain directions, and, consequently, as the head increased in size, it would, of course, grow in those directions in which this resistance was not opposed. The result thus obtained was simply an exaggeration of the natural differences which had now been pointed out. Among the Cherokee Indians the front part of the head was compressed, so that there was apparently no forehead, while among the Natchez the back part of the head was compressed, so that from the external form one would say that there was no occiput or cerebellum; yet as regards function there was absolutely no difference between the brains in the two forms of heads.

THE PRESIDENT remarked that he had not known, beforehand, in what direction the investigations of Prof.

Dalton would lead, and he had not therefore prepared himself specially to make any contribution to the subject now before the Academy; but he thought it might be of interest in connection with it, to recall that some years ago, probably fifteen or twenty, the *Obstetrical Journal* had published a number of papers by Mathews Duncan, and other writers of eminence, in regard to the influence of parturition in forming the shape of the human head. To obtain what light he could upon the matter from a practical investigation, he made some inquiries in connection with the lying-in department of Bellevue Hospital, with the aid of the House-staff. During a service of nine or ten months, the heads of one hundred and thirty-two infants were examined immediately after birth, and again at the expiration of eight days. As was well known, about eighty-five out of every one hundred children born, presented with the head in the left occipito-anterior position, and that during the process of parturition, especially in tedious labors, the form of the head became moulded and adapted to the maternal parts and often greatly changed. There was great compression of the long diameter, and a corresponding dilatation of the short; while there was a marked bulging out of the right side of the head to fill the unoccupied space left in the right oblique diameter of the pelvis. Of course, the pressing out of the head would be in the opposite direction in the right occipito-anterior position. At the time mentioned, the question was discussed a great deal, whether this compression during labor permanently influenced the head or affected the functions of the brain afterward. In the investigation made at Bellevue Hospital, it was found very generally that the disproportion between the two sides of the head which was noted immediately after birth, had disappeared by the end of eight days, but in some instances this disproportion was more or less prolonged. Dr. Barker said that if he saw a child (whose delivery he himself had not attended) within forty-eight hours after birth, he could almost invariably tell from the shape of the head whether the occiput had pointed towards the right or the left, provided there had been an anterior position of the vertex. In posterior positions the case was different, on account of the rotation which was requisite before the head could be born. Whether any difference in function was occasioned by the compression and change of shape resulting from parturition, he was not prepared to say. There was another point to which he would call attention for a moment. He would like to know whether if, ten years from now, Dr. Dalton presented diagrams of the same heads which he had to-night, the outlines would be precisely the same as at the present time. For his own part, he felt pretty sure that the form of the head changed more or less in adult life, and more at an advanced period of life. He had been led to this opinion by the fact that his hatter had found, in his own case, that his head changed from time to time.

DR. LEONARD J. CORNING considered the researches of Dr. Dalton of deep interest because, in the first place, they showed a most perfect method of investigating asymmetry of the cranium; and, secondly, on account of the inferential remarks which he had offered in regard to the possible effects resulting from differences in symmetry. His idea that external compression did not have the effect of causing a dwarfing and atrophy of the portion of the brain beneath, but that these parts were simply pushed into other locations was a very suggestive and valuable one, he thought. The hypothesis that the form of the brain had not so much to do with its functions as the amount of surface presented by the gray matter, whether spread out over a wide area or over deep and complex convolutions was one that was fraught with the deepest interest. It was exceedingly common at the present day to bring up at criminal trials, where the sanity of the prisoner was in question, the idea that asymmetry of the head indicated an unbalanced brain, and he thought that a great deal of capital had been made out of this without any measurable basis of facts upon which to found data. In the case of Guiteau, for instance, he had never been satisfied as to the validity of the argument that because his head was asymmetrical he was not of sound mind; and he thought, therefore, that Dr. Dalton had rendered to science a very valuable service in advancing this hypothesis. It seemed to him that it was plain that there might be flattening in one part of the cranium and protrusion in another, and yet the organs beneath be presumed intact; and he thought, therefore, that weight had been attached to this matter of asymmetry which was not warranted by facts.

DR. DAVID WEBSTER said that in his own case he had noticed that he required, from time to time, slightly different sizes in his hats, but he had supposed that this was probably due to the amount of thickness of the hair at the time. He would like to inquire whether Dr. Dalton had noticed any changes in adult heads.

DR. DALTON, being called upon to close the discussion, said that this idea of changes in the adult head suggested by Drs. Barker and Webster, was a new one to him, but it was a very interesting one, and one that he would like to see investigated. It was well known that other parts of the body differed very materially as life advanced, and it was quite possible that this might be the case with the cranium also. It seemed to him extremely probable, from what Dr. Barker had said, that the twist which the head of the child received during parturition disappeared shortly after birth, but that in a few cases the obliquity remained permanent. As the result of his investigations, he would say that we could not conclude from the existence of asymmetry in the cranium that there was a corresponding difference in the brain itself.

DR. P. A. MORROW then read a paper entitled

AN IMPROVED METHOD IN THE TREATMENT OF CERTAIN FORMS OF SKIN AFFECTIONS.

The method referred to, he said, was the application of medicinal substances by means of fixed adhesive dressings. Among these dressings were the application of drugs in combination with collodion and gutta-percha, and by means of gelatine, which could be rendered more pliable by the addition of glycerine, then painting a layer of the medicinal substance required over the part and covering it with a layer of collodion, and the incorporation of the drugs with adhesive plaster, the basis of which was gutta-percha. There was nothing of novelty to dermatologists in all this, but the method had only come into use within the last year or two, and since it was not alluded to in any of the text-books on diseases of the skin, he thought that it might be of interest to the

profession at large to present it. He claimed nothing original in what he had to say, except so far as his own experience confirmed the observations of others, and his aim was simply to present, in a brief manner, the mode of preparation of the dressings alluded to, the conditions in which they were appropriate, their therapeutic value, and the clinical results which had been obtained by their use.

This method of making fixed adhesive applications, he believed, was undoubtedly a decided advance in the field of cutaneous therapeutics. The old modes of applying medicinal substances, while admirably adapted for their purpose in many respects, and still the best in a large number of cases, had certain disadvantages. Thus, when drugs were employed in the form of powder, the powder was easily rubbed off, and if applied over an exuding surface an irritating crust was very liable to be formed; while lotions quickly evaporated. The ointment had, as a rule, always been the most efficient and convenient form in which to make applications to the skin; but this, too, was easily rubbed off, and was in a measure a cumbersome and uncleanly dressing. Dr. Morrow then quoted a passage from Erasmus Wilson in regard to the influence of fashion in cutaneous therapeutics. At one time there was a great outcry against the use of all sorts of unguents, and the water-dressing was unduly lauded. The ointment, however, survived the attacks made against it, and again came into general use; but still it would always be open to the objection of uncleanliness, and of being offensive to the taste of the fastidious. Again, it was impossible to give ointments sufficient solidity to exclude the air, and by diffusing themselves over healthy skin in the vicinity of the lesions to which they were applied, they were very liable to propagate disease. At the same time, he did not mean to detract from the real and substantial efficiency of this kind of application, for which in many conditions no equally good substitute had as yet been found. The fixed dressing was not designed to revolutionize the treatment of skin disease, but simply to supplement the older methods in use, and its application was without doubt comparatively limited.

Dr. Morrow then went on to say that cutaneous pharmacy had not kept pace with that of internal medication, but of late much improvement in this respect had been noted. He then enumerated some of the drugs which, during the past few years, had gained repute in cutaneous therapeutics, such as chrysarobin, pyrogallic acid, salicylic acid, iodoform, and naphthol. Some of these were very powerful agents, and it was necessary not only to be familiar with their properties, but to know how to use them. Chrysarobin was undoubtedly the most efficient remedy now at our command for the treatment of psoriasis, especially in chronic cases and those which had resisted other forms of treatment. Its range was limited, however, as it was contraindicated in acute cases generally, in children, and in patients with tender and irritable skins; while if applied to the head it was apt to produce puffiness of the face and eyelids and conjunctivitis. As ordinarily applied, it was very irritating to the surrounding skin, discolored the hair, and stained the clothing and everything with which it came in contact. So successful, however, was the effort to obviate these inconveniencies and injurious effects by combining the remedy with collodion and gutta-percha —for which the credit was largely due to Dr. George H. Fox—that it led to the combination of a number of other drugs with the same class of substances, and to the establishment of fixed adhesive dressings as a recognized method of treatment in diseases of the skin. The medicated collodions had the advantage of being always ready for use, as well as perfectly cleanly. Pick, of Prague, was the first to make use of gelatine for the same purpose. Fifty parts of gelatine were dissolved in a hundred of water, and to this the medicament to be used was added. When the preparation was to be applied, it was first placed in a convenient vessel and dipped in hot water. This constituted an admirable and flexible dressing, and it could easily be removed by the application of hot water. Pick claimed that it had the advantage of being transparent, so that the lesion under treatment could be viewed through it. This transparency, however, Dr. Morrow had found a rather uncertain element, depending upon the drug which was combined with the glycerine. Unna, of Heidelberg, had modified Pick's gelatine dressing by adding to it five, ten, fifteen, or twenty per cent. of glycerine, according to circumstances. Dr. Mitchell, of Philadelphia, now manufactured gelatine plasters of various kinds, with which he had obtained very satisfactory results. The only objection that he had found to them was that they sometimes deteriorated by keeping; but he thought that this difficulty could probably be easily obviated by the addition to them of a small quantity of salicylic acid, or other antiseptic. Those which he at present was using were made by Messrs. Hays & Sons, of New York. Prof. Auspitz had devised a useful dressing which he designated *traumaticin*. It was a ten per cent. solution of refined gutta-percha dissolved in chloroform, and resembled the *Liquor guttæ perchæ* of the United States Pharmacopœia. It was claimed for the traumaticin that it was a delicate, neutral, durable, and invariable dressing, which was more elastic than gutta-percha plaster. The latter was a decided improvement over the ordinary lead and resin plasters, and was of especial service in certain localized disorders affecting the hands and fingers, the crease of the thigh, the toes, the anus, etc.

Dr. Morrow next proceeded to speak of the verdict of clinical experience in regard to the new methods. In psoriasis, he said, the results obtained by the use of chrysarobin in connection with them had proved eminently satisfactory. He spoke of the success achieved with it in the treatment of chronic eczema, prurigo, tubercular syphilis, and other affections by Auspitz, Benier, R. W. Taylor, and others. He also mentioned some of the results obtained, in Europe, with naphthol, salicylic acid, and other remedies, and said that iodoform collodion was used in immense quantities at Billroth's clinic. He then spoke of his own experience, and said that in psoriasis, as well as in chronic eczema with excessive pruritus, he had for the most part met with very satisfactory results with chrysarobin. In acute eczema he had been much pleased with the use of a gelatine dressing containing ten per cent. of oxide of zinc, and he related a case of chronic eczema of the face with extreme itching, in which a single application of this, with the addition of one per cent. of carbolic acid, gave complete and instant relief. Each form of application which had been mentioned, he said, had special advantages in certain cases and conditions, and

he then gave a summary of the advantages of these methods somewhat as follows:

1. The complete protection of the part, and exclusion of air.

2. The securing of the direct action of the drug employed upon the parts affected.

3. The maintenance of a gentle and uniform compression.

4. Complete cleanliness.

The following general conclusions were reached by Dr. Morrow:

1. The adoption of the method of fixed adhesive applications marks a decided advance in cutaneous therapeutics.

2. It is admirably adapted for certain special purposes.

3. It constitutes the most efficient means of treating hyperæmic conditions accompanied by epithelial aggregations, derangements of the capillary circulation in certain neurotic conditions, and in circumscribed lesions generally.

DR. BRONSON said that what he particularly admired in Dr. Morrow's paper was the conservative manner in which he had dealt with the subject. The method under discussion was now the fashion, and the chances were that the thing would be overdone. The writer had said almost all that there was to be said upon the subject, and he had done it well. The method was not one capable of universal application. In regard to the gelatine preparations, he differed somewhat from Dr. Morrow, as he considered them of comparatively little value. It was quite difficult to prepare them for convenient application; but the case was different with the gutta-percha and collodion preparations, which were easy to apply, and which he thought would, in time, entirely supersede the gelatine of Pick. He could fully endorse Dr. Morrow's statements in regard to the efficacy of the method in general, and he believed that it was best suited to diseased conditions in which there was a certain degree of thickening and the presence of an accumulation to be removed. He did not think the value of the preparations mentioned depended on the protection which they gave so much as on the facilities which they afforded for coaptation of the remedy to the part affected. There was another disadvantage connected with the use of the gelatine, more particularly in cases in which there were fissures, which he had neglected to mention, and that was that it acts too quickly. Chrysarobin or chrysophanic acid required to be rubbed in very thoroughly, and while the use of the gutta-percha and collodion permitted this, with the gelatine there was not time for it. In addition to psoriasis, he considered this remedy of special value in two affections: in eczema of circumscribed area, without much weeping, and characterized by marked itching, and in lichen planus, attended with intense itching. Carbolic acid could be employed in very much greater strength when combined with these fixed dressings than in any other way.

DR. G. P. JACKSON said that he had found so much difficulty in applying the gelatine preparations that he had now given them up, and in the few cases in which he had used them the results had not proved satisfactory. The collodion preparations he had employed with success, particularly in psoriasis and eczema.

DR. SHERWELL, of Brooklyn, thought that there would be difficulty in applying these medicated preparations in certain circumstances, as, for instance, the gelatine over exuding surfaces, or the collodion upon the hairy scalp.

DR. MORROW then closed the discussion. Dr. Bronson's criticism in regard to the gelatine preparations, he said, might be reasonable from his stand-point, but he himself did not find any inconvenience in using them. Their efficiency depended largely on the careful preparation of the glycerine and gelatine, as well as the drugs used in combination with them. The first preparations which he had employed were all defective, and if he had rested content with this first experience, he would, no doubt, like Dr. Jackson, have given up the use of gelatine altogether. With those which he now used in his practice he secured an admirable elastic coating, which remained for a number of hours. With regard to Dr. Sherwell's objection to using gelatine over exuding surfaces, the difficulty was merely a theoretical one, which he himself had anticipated before applying it under these circumstances, but which he had found by experience did not exist practically. He thought that as the pharmaceutical preparations became more perfect, gelatine would be more generally used than it was now.

As to the difficulty of applying collodion or gutta-percha to the hairy scalp, if the affected part were not free from hair, as was likely to be the case, it was his custom to have it shaved or the hair cut close with the clippers used by barbers. He had not ventured to apply chrysarobin to the scalp after one or two unfortunate experiences which he had had with it; although when used in combination with these fixed dressings he believed that no ill-effects would result from its use in this position. There was a theoretical objection that with a layer of gutta-percha or collodion between the drug and the diseased surface, the remedy might not produce its appropriate effects; but practically it had been found that this was not at all valid. A parallel case was seen in the vesicating action of cantharidal collodion, and another proof was seen in the case that Pick had reported, in which systemic poisoning was produced by pyrogallic acid applied by this means.

CORRESPONDENCE.

"A YEAR'S WORK IN OVARIOTOMY."

To the Editor of THE MEDICAL NEWS.

SIR: I thank my friend, Dr. Sutton, for correcting a careless slip of my pen, and for the explanation of his remarks from which the misquotation was made. I also wish here to beg Mr. Tait's pardon for misrepresenting him. Yet, in self-defence, let me say that I think that my interpretation of Dr. Sutton's remarks was not altogether an illegitimate one. The inference that I drew from them was, until explained otherwise by Dr. Sutton, that Billroth was the only European operator who did not refuse any case of ovarian tumor, however unpromising it was.

Dr. Sutton's remarks are as follows: "Dr. Keith employs only one assistant, and Mr. Tait uses one. In Billroth's clinic there are a great number of assistants, but it must be recollected that he refuses to operate upon nothing that deserves the chance of life, and his

statistics approach more nearly to the statistics of our own country than those of any other operator abroad. Sixty-five per cent. of recoveries are about as good a showing as he can give in laparotomy. But I will say this: That in no place did I see such cases operated upon as were operated upon by Billroth. He operates upon everything. So far as Mr. Tait is concerned, he *does* not remove *many* [the italics are mine] large tumors—those which weigh from sixty to sixty-five pounds, with extensive adhesions, etc." [1]

I fully agree with Dr. Sutton, that private hospitals are better places for abdominal operations than the patient's own home. Yet, the greater mortality of those of my cases operated on at their homes, I attribute less to hygienic causes than, first, to the extreme prostration of the women who, after several tappings, were too ill to travel; secondly, to my being assisted by those who were not familiar with the technics of the operation; and, lastly, to my not having the after-care of these cases.

Very respectfully,

WILLIAM GOODELL, M.D.

CINCINNATI.

(*From our Special Correspondent.*)

BURKISM.—Never in the history of this city have the annals of crime exhibited so many or such brutal murders, as during the past winter. The last of these, a triple murder, has kindled in Cincinnati much the same furor as was aroused in Edinburgh, in the early part of this century, when first the crimes of the infamous Burke became known.

On the afternoon of February 15th, a negro who has been engaged for several years as a resurrectionist, called upon the Demonstrator of Anatomy in the Medical College of Ohio, and offered to bring him three subjects. Early the same evening he went with an accomplice, to the house of an aged colored man, who lived with his wife and an adopted daughter, in Avondale, in the suburbs; these three they killed and immediately took their bodies to the college, firing the house to conceal the crime. The marks of violence upon the bodies were not sufficient to attract attention without closer examination than is usually given to subjects when received, and the suspicions of the Demonstrator were not aroused until almost a week after; he was notified by the police that no bodies had been found in the burned building, and he was asked to examine any bodies he had received for marks of violence. He then notified the authorities, and has since identified the negroes who sold him the bodies. These have confessed the crime. The newspapers, particularly one or two sensational sheets, have been ever since filling their columns with abusive articles, intended to injure as much as possible, not only the Demonstrator, who unfortunately is so immediately involved in the case, but also the entire Faculty and the College itself.

During the last few years a large part of the material has been provided by a Practical Anatomy Act, which permits the giving of unclaimed bodies to the colleges, and it is believed the supply thus provided for would be sufficient to meet the demand, but the authorities of many of the public institutions appear determined to avoid complying with the law. The necessities of medical education, therefore, have made it customary to receive bodies from resurrectionists as well. Now that legislation on medical questions is becoming the fashion, we may perhaps have an amendment to the Act, so as not only to permit but to compel the giving of bodies to the colleges, and thus make the law similar to that which now prevails, with such excellent results, in Pennsylvania.

[1] Transactions of the American Gynecological Society, vol. viii. p. 84.

CHICAGO.

(*From our Special Correspondent.*)

RUSH MEDICAL COLLEGE.—The annual commencement exercises of Rush College occurred on the 19th instant. The number of graduates was one hundred and sixty-seven, one receiving the honorary degree. The gentleman on whom this was conferred was Dr. A. L. Justice, of El Paso, Texas.

The Alumni of the College were entertained in the evening at a banquet at the Grand Pacific Hotel. Four hundred alumni and friends of the College sat down to this dinner. Subsequently a life-size portrait of President J. Adams Allen was presented to the Faculty.

The hospital, which was begun by the Trustees of Rush College, adjacent to the College building, has been transferred to the Presbyterian order, and will be known as the "Presbyterian Hospital." It is being rapidly pushed forward to completion, and ought to be ready for occupancy in eight weeks. The College Faculty retains professional control of it.

SCHOOL OF OPHTHALMOLOGY AND OTOLOGY.—The medical staff of the Illinois Charitable Eye and Ear Infirmary, located here, have established a school of ophthalmology and otology for practitioners. The course of instruction will consist of didactic lectures and drill, and daily attendance upon the service of the Infirmary, which offers the amplest possible clinical opportunities. Probably more than two hundred different patients are treated each day in the rooms of this institution. Of these, slightly more than half are out-patients. The staff consists of Drs. Holmes, Hotz, Ware, Montgomery, Schaefer, and Bishop, surgeons; Drs. Gardiner, Bettmann, Gilmore, Colburn, Harper, Kewley, and Morgan, assistant surgeons.

ANATOMICAL MATERIAL AND THE ANATOMY ACT.—Perhaps at no time before, in Chicago, has there been so much public talk and discussion of the subject of anatomical material as this winter. The colleges have had some difficulty in procuring a sufficient supply, but have generally succeeded, and their classes will go out having fulfilled the requirements as to dissections. There is a State law which permits the bodies of unclaimed paupers to be used for anatomical study. For ten years the law has been in operation, and the colleges have not been under the necessity of obtaining material elsewhere till this season. Now the County Commissioners who elect, and hence control, the wardens of the county hospital and county almshouse, have forbidden these officials paying respect to the law on pain of dismissal. As a result, the colleges have to pay high prices for

material, which has led to activity among those willing to engage in the business of procuring subjects. Two medical students are now in jail in DeKalb County for resurrecting. Their case is peculiarly unfortunate, because, if they are guilty, their conduct was both unnecessary and reprehensible. The bodies of two persons well known were stolen and brought to Chicago. Their discovery in the colleges here led to much excitement.

MUNICH.

(From our Travelling Correspondent.)

THE HYGIENIC INSTITUTE IN MUNICH was the first one built in Germany for the practical teaching of hygiene, where it could be taught in an objective manner, and where students could be made familiar with the various procedures, modes of investigation, etc., involved in its scientific study. Now there are three or four similar institutions in various places in Germany, a large one is being built in Vienna, and Prague will probably have two, one for each university. The building in Munich is a handsome brick structure, and cost when complete eighty thousand dollars. The course of study given in the Institute is not obligatory on the medical students; only those intending to enter into the service of the State being obliged to pass a practical and theoretical examination in hygiene. The course given to such students is a rather thorough one, embracing the study of the air, water, ground, clothing, food, etc., in their relation to health. The examination of the ground with reference to its moisture, the height at which the ground water stands, the organisms it contains, receives here great attention.

THE SPREAD OF LOWER ORGANISMS IN THE GROUND.—A very interesting series of experiments have just been concluded by one of the assistants, on the spread of lower organisms in the ground, their ascent from a depth below the surface to the surface, and the circumstances which favor or are inimical to this. A flask of sterilized nourishing solution was connected by a glass tube containing sterilized earth of a known composition, with another flask which contained a fluid containing certain definite bacteria. The sterilized flask was above the other, and the end of the tube containing earth projected above the surface of the fluid; the other end passed into the fluid containing the bacteria. By placing some of the earth from the end of the tube in the sterilized solution, it could easily be seen when it contained organisms. These, of course, could only have ascended through the earth. As the bacteria used were a known and easily recognized species, there was no danger of mistaking an accidental infection for the result of the experiment. It was found that conditions favoring capillary attraction, the fineness of the particles of earth, also most favored the ascent of the organisms.

These experiments are, of course, of especial interest in regard to the ascent of pathogenic bacteria from the body of the cadaver to the surface of the earth. Pasteur, as is well known, sought to account for this by his rain worm theory, that the worms in their passage through the soil ate the spores, and on reaching the surface discharged them in their moulds, a theory which was certainly very brilliant in its conception, but not supported by facts.

In the investigation of water, besides its chemical constitution, particular study is made of the organisms contained in it. Pure cultivations of these are made after Koch's gelatine method, and then they are studied as to their physiological action by inoculations on animals.

RELATIVE VALUE OF THE VARIOUS CLOTHING TEXTURES.—Another of the assistants was carrying out an elaborate system of experiments on the relative value of the various clothing textures, especially with the so-called normal clothing of Dr. Jäger. This consists entirely of woollen materials, the stockings, drawers, and undershirt being made in one piece. Every toe in this remarkable garment is enclosed in its own particular—well we can hardly say toe, nor even finger, but the stockings are like gloves. Over this a woollen shirt is worn, and the outer clothing is made out of a particular woollen cloth, and the coat and vest button close up to the chin. The clothing may be immensely comfortable and healthy, but it is not handsome. The experiments were to determine how much real value the system had.

THE CHOLERA EPIDEMIC IN EGYPT.—The following account of the recent cholera epidemic in Egypt, and the means employed for its suppression, has been furnished to the State Department by the Consul-General at Cairo, and forwarded to the Marine-Hospital Service for its information:

"With reference to the painful and widespread epidemic which affected all classes of the population of Egypt last summer, I beg to submit to you the following carefully made observations respecting its development and character.

"I must begin by saying, Egypt is a country in which hygienic or sanitary regulations have for a long time been, and still are, entirely neglected. There obtains here a condition of things most unfavorable to health, due to the apathy and almost criminal negligence of the authorities, and to the habitual want of cleanliness of the native population; that which is unclean and impure, the dregs and refuse of dirty water, are deposited in the public streets, the open squares, and narrow passages of all the towns and villages in Egypt. The construction of underground conduits or sewers to carry away water and impurities was never projected in any Egyptian town or village. The inevitable consequence was, that in the houses of the natives most unhealthy and impure elements have been prevalent for a prolonged period. In the respectable European quarters of the towns is there only an exception of the regulations for the protection of the public health.

"The Nile Delta, by reason of its well-known insalubrity, would be a district of permanent abode for contagious disease if the great heat which is so prevalent did not counteract miasma, and if the clear air of the desert did not, likewise, frequently and thoroughly purify the atmosphere.

"Since the reign of Mohammed Ali, the first Viceroy of Egypt, sanitary regulations and ordinances for protection of the public health have often been promulgated, and the efforts of European physicians exerted to ameliorate this condition as far as the popular and re-

ligious sentiments of the country would permit. But since the revolt of Arabi Pasha against the constituted authority, when most of the European functionaries were removed from office in order to make room for incapable natives, the direction and control of the sanitary public passed into the hands of Arab doctors, whose want of knowledge and venality interfered with its efficient working. Previous to 1879, the year in which Tewfik Pasha, the present Khedive, ascended the throne, the Sanitary Board in Alexandria was under the direction of a European doctor and a representative European council, lay and medical.

"As already explained, about three years ago, the sanitary service became an arrangement of purely native origin, and was stationed in Cairo. A sanitary maratime and quarantine council, composed of delegates from the different consulates, and under an Arab director, was likewise formed in Alexandria after a protest of the consuls in that city who are in the service of the various European States. The council of Alexandria does not examine or consider matters which relate to the discovery and application of remedies for diseases. Its sole purpose is to prevent the sudden appearance in Egypt, from foreign countries, of epidemics, and, in such an event, to order the necessary preventive measures to be taken. Such was the condition of the public health, and such the character of the sanitary authorities, when the cholera broke out at Damietta, towards the end of June last.

"Cholera has invaded Egypt in the form of a great epidemic five times since its first appearance, which occurred in the year 1848. It had always been introduced from Asia, especially from India, which is its natural home. Several times cholera has made its appearance in adjacent countries. And two years ago it was even brought into Egyptian territory by pilgrims from Mecca; but, owing to the strict precautions taken, and to quarantine regulations, this country escaped the dreadful calamity.

"In 1883, some very adverse circumstances contributed to the introduction of cholera into Egypt and to its rapid development. The insurrection which broke out in June, 1882, made worse the bad hygienic condition of the country. This was followed by epizooty, a strong bovine typhus, which was prevalent to the end of November, 1883. Thousands of animals fell victims to said disease, and many hundreds, not to say thousands, of them were thrown and left to decay in the canals, the waters of which were made use of to irrigate the fields and to meet the daily necessities of the neighboring population for drinking purposes. These are the acknowledged causes which have subjected Egypt to this baneful and troublesome epidemic. Its invasion is to be ascribed to the policy adopted by the British authorities, who never permitted any restrictions to be used by the Egyptian sanitary authorities which would interfere with their Indian trade; consequently, the Government of Egypt was compelled to allow the free passage of vessels engaged in the trade through the Suez Canal, and to stop at its different ports.

"During the months of May and June of last year, there was at Bombay and Calcutta a recrudescence of cholera, which had a tendency to assume an epidemic form. The sanitary maritime and quarantine council at Alexandria having been apprized of the impending danger, and energetically pressed by the Turkish sanitary authorities at Constantinople, proposed some measures and quarantine regulations to be applied to all vessels coming from India. But the English government, whose influence in Egypt is unlimited, has, in several ways, prevented the execution of the projects of the above-mentioned council of Alexandria, and, in consequence, every vessel arriving from India had free communication with all ports of the Suez Canal. This unrestrained and direct communication of Egypt with countries in which cholera prevailed, was the real cause of the importation of the disease.

"Another and a local cause of the development of this malady and its rapid spread, was occasioned by the following circumstances: Damietta, where the cholera last year first appeared, is an exceedingly unhealthy town. The exhalations there from decaying matter cause, every summer, ophthalmia and dysentery. It is also subject, during spring and summer, to the kamsin, a most oppressive hot wind, which carries with it clouds of dust and sand. When the cholera which, according to the official report, appeared at Damietta on the twenty-first of last June, in a very short time it became alarming in its progress. No remedies were employed. There was a thorough absence of medical attendance, and the poor natives, not knowing how to treat it, obstinately abandoned themselves to fate, and perished by thousands. About the middle of last June a great fair was held at Damietta, which attracted over fifteen thousand visitors from neighboring and distant villages. At the time this fair was held, several Indians visited Damietta for purposes of trade, and also a certain number of coalmen and firemen employed on English steamers coming from Bombay. According to authentic sources of information, these are the circumstances which favored the rapid development of this insidious disease.

"In conformity with the advice of native doctors, the Egyptian Government immediately formed sanitary cordons around the infected districts, in the hope of checking the spread of the epidemic. These sanitary cordons, however, served practically no purpose. They were insufficiently well organized, and could not prevent intercourse taking place with towns and villages where this pestilence prevailed. These cordons fell into disuse when the cholera, following the high roads of travel by river and railway, reached Cairo, whence it extended in length and breadth over Lower and Upper Egypt, with the exception of Alexandria, which subsequently was also invaded, and where, indeed, this epidemic proved to be less violent than elsewhere. This was due to the sanitary measures taken by the European Colony.

"On the first appearance in that city of this epidemic, there was formed a sanitary commission by the consuls and prominent members of the European Colony, presided over by a Minister or Governor, upon whom the Egyptian Government conferred full power to adopt effective measures for preventing the breaking out and progress of the disease. Owing to the pecuniary means placed at its disposal by the Government and private individuals, this Commission rendered great service to the inhabitants. In Cairo there were also two international commissions, based on the same principle as that of Alexandria, of which one was composed of ministers, English generals, and high functionaries, European and

native; the other one was formed of consuls of the different powers and prominent members of the European colony, and placed under the presidency of the prefect of police. This last commission has labored with the greatest energy and zeal in the execution of its task. It had at its disposal Government funds and full power of action. I must also state there were a number of doctors, engineers, and competent, useful men in these commissions who were adapted for this office of devotion.

"These commissions made every effort to promote the public health. They earnestly endeavored to free the towns and villages of all infectious matter, to establish hospitals and ambulances, regulate burials, inspect market-places, isolate those persons infected with cholera symptoms, and to destroy by fire those houses in which this disease prevailed.

"The cholera penetrated as far as Luxor, one day's journey below the first cataract on the Nile; more than sixty thousand of the inhabitants were made victims to this disease. For the purpose of examining the nature, origin, and method of medical treatment, the French and German Governments sent to Egypt medical commissions composed of eminent savants. The Russian and Turkish Governments sent delegates here for the same purpose; and the English Government was likewise represented by twelve medical men and twenty Indian nurses. These, however, arrived in Egypt too late to be of any service, and were of great expense to the Egyptian Government.

"As official delegate from England, Surgeon-General Hunter was likewise sent to Egypt during the prevalence of the cholera, and remained there for three or four weeks. In his official report to the English Government, he declared in a positive and peremptory manner that the cholera in this country was not introduced last year from India, but, on the contrary, had become a disease of an endemic nature; and as he could not deny the existence here of Asiatic cholera, he endeavored to prove that its germs had remained in Egypt, in a concealed state, ever since 1865, and that in 1883, the hygienic condition of this country being very bad, its germs had taken on a very unusual degree of intensity.

"These opinions of Surgeon-General Hunter, who is an expert and well-versed in his profession, are not shared by any medical practitioner here, much less by the commissions and scientific delegates of the European governments, who have expressed themselves frankly and clearly with regard to the character and the introduction of the cholera from India into Egypt last year.

"The English army of occupation, in Egypt, withdrew from towns where the cholera made its appearance and retired into adjoining deserts where the quarantine was enforced. By this means, exposure to the disease was in a great measure avoided. From a total number of seven thousand British soldiers stationed in this country, only one hundred and forty-six succumbed under this calamity.

"Until very recently a few sporadic cases were still reported in Alexandria; but everywhere minds have now recovered their settled state and calmness. And the careful thought of the government has been occupied in the reconstruction of the sanitary board, which during the disease, and even previous to its outbreak, manifested a very great incompetency. The public voice in Egypt has given expression to a sincere wish for the change and radical reform of the sanitary service. The first person who officially proposed a change of the sanitary board, was Surgeon-General Hunter, and afterwards the English Government.

"Mr. Clifford Lloyd recently appointed Under-Secretary of State for the Interior, and previously Inspector of Reforms in the Ministry of the Interior, elaborated a plan for reform of the Sanitary Service. By khedivial decree, an International Commission composed of foreigners and natives, has been appointed to consider this project, in compliance with which the Board of Health has been set aside, and in its place a Director of Sanitary Police appointed in the Ministry of the Interior, dependent in all matters upon the Minister, and having for assistance a Medical Council, which enjoyed the sole privilege to meet for consultation.

"By these means the Sanitary Service will be better looked after and conducted, in all that regards the public health of this country. Moreover, the Maritime and Quarantine Council of Alexandria, will remain permanently in existence as an International Sanitary Commission, and with the provision that its Director should be a European, and not a native doctor."

The New York Polyclinic.—The Quarterly Circular Announcement of this school states that for the first four months of the present session one hundred and seven practitioners were studying in its special classes, while for the first fifteen months of its existence the classes have numbered over two hundred and sixty. The managers, encouraged by the success of the school, have purchased a large property, which they announce they will immediately convert into a thoroughly equipped clinical school and hospital. The Faculty hold seventy positions in the various hospitals and dispensaries of New York, and have in working order a clinical organization so large and complete that the supply of cases for study and demonstration they believe to be equal to every want.

The German Cholera Commission.—The Minister of the Interior, of Germany, has just received the fifth report of the Commission sent out by the Imperial Board of Health, first to Egypt, and then to India, to inquire into the causes and cure of cholera. The report establishes the fact that there is a close connection between the disease and certain bacilli of a specific character which were found with the aid of the microscope in the bodies of cholera patients.

Sanitary Convention in Michigan.—A Sanitary Convention will be held in Hillsdale, Michigan, on Thursday and Friday, April 17 and 18, 1884, under the auspices of the State Board of Health.

The Galligo Prize.—La Societa Medico-Fisica, of Florence, has recently awarded the first triennial Galligo prize to Drs. A. Bianchi and C. Balocchi for their essay on "Regressive Spinal Paralysis of Infancy."

The British Medical Association; Meeting at Belfast. — The fifty-second annual meeting of the British Medical Association will be held on July 29, 30,

and 31, and August 1, 1884, at Belfast, under the presidency of James Cuming, M.A., M.D., F.K.Q.C.P.I., Professor of Medicine, Queen's College, Belfast. The Address in Medicine will be delivered by Sir Andrew Clark, Bart., M.D., F.R.C.P., Physician and Lecturer on Clinical Medicine, London Hospital. The Address in Obstetric Medicine will be delivered by George H. Kidd, M.D., F.R.C.S.I., Master of the Coombe Lying-in Hospital, Dublin. The Address in Physiology will be delivered by Peter Redfern, M.D., F.R.C.S.E., Professor of Anatomy and Physiology, Queen's College, Belfast.

Communications in reference to the meeting of the British Medical Association at Belfast, should be addressed to the Hon. Local Secretaries, John Moore, M.D.; Alexander Dempsey, M.D.; John W. Byers. M.A., M.D.

Visitors going from America to attend this meeting can travel by any of the following routes:

1. A "Cunard" steamer will leave (*a*) New York on Wednesday, July 16, arriving in Queenstown about the following Thursday week, July 24. (*b*) Boston on Saturday, July 19, reaching Queenstown the following Monday week, July 28.

2. A "White Star" steamer will leave New York on Saturday, July 12, and on Saturday, July 19; due at Queenstown about July 20 and July 27.

3. An "Inman" steamer will leave New York on Tuesday, July 15; due at Queenstown about July 23.

4. An "Allan" steamer will leave Quebec on Saturday, July 19, arriving in Londonderry about the 26th or 28th of July.

5. An "Anchor" steamer will leave New York on Saturday, July 19; due at Londonderry on July 29.

Londonderry is ninety-five miles from Belfast, and trains run daily between the two places.

The route from Queenstown to Belfast is from Queenstown to Cork, Cork to Dublin (one hundred and sixty-five miles by train), and Dublin to Belfast (one hundred and thirteen miles).

MEETING OF THE INTERNATIONAL MEDICAL CONGRESS AT COPENHAGEN.—The time of the meeting of the British Medical Association at Belfast has been fixed so as not to interfere with the International Medical Congress, which is to begin at Copenhagen on the 10th of August.

A steamer will leave Hull (England) on August 2 and 9 for Copenhagen; and on August 5 a steamer will leave Leith (Scotland) for Copenhagen. Both these places (Hull and Leith) can be reached on any day by leaving Belfast on the previous evening by the cross-channel steamers. Visitors, after attending the meeting of the British Medical Association in Belfast, will have ample time to travel to Copenhagen for the Congress.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending February 16, 1884, indicate that erysipelas, remittent fever, scarlet fever, and inflammation of the bowels have increased, and that diarrhœa, pneumonia, influenza, and typhoid fever have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending February 16th, and since, at eleven places, measles at ten places, and smallpox in Bath township.

OBITUARY RECORD.—DR. GEORGE ENGELMANN, of St. Louis, died of pneumonia on February 4, in the seventy-sixth year of his age. He was born in Frankfort-on-the-Main in 1809, and came to the United States in 1832, after having received his education at the Berlin, Heidelberg, and Würzburg Universities. He went to St. Louis immediately upon his arrival in this country, and there began the practice of medicine and the study of the natural sciences. He was one of the founders of the Western Academy of Science in 1836, and later, one of the originators of the St. Louis Medical Society. In 1856 he was largely instrumental in founding the St. Louis Academy of Science, and was, for many years, president of that body.

Dr. Engelmann won an enviable reputation throughout the United States and Europe, of being one of the finest botanists in America. For forty-seven years he made it a part of his occupation to take meteorological observations several times a day, and only discontinued this practice two days before his death. He was the oldest practitioner in St. Louis. His only child is Dr. George J. Engelmann, of St. Louis.

—— Died at Edinburgh, on February 11th, DR. JOHN HUTTON BALFOUR, Emeritus Professor of Medicine and Botany in the University of Edinburgh, Regius Keeper of the Royal Botanic Garden, and Queen's Botanist for Scotland. He was born in 1808. He was a member of many learned societies both at home and abroad, and was the author of a variety of books and articles on botany, including the *Manual of Botany* and *Botany and Religion*.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 19 TO FEBRUARY 25, 1884.

BROWN, JOSEPH B., *Lieutenant-Colonel*, and BILLINGS, JOHN S., *Major and Surgeon*.—Directed to attend the International Health Exhibition in London, and, as delegates, the International Medical Congress at Copenhagen, to be held in May and August next, respectively; also to include Berlin in their route to or from Copenhagen, and to be governed by special instructions from the Surgeon-General in complying with this order.—*S. O. 44, Par. 8, A. G. O.*, February 21, 1884.

WOODWARD, JOSEPH J., *Major and Surgeon*.—Leave of absence still further extended six months, on account of sickness.—*S. O., 44, Par. 11, A. G. O.*, February 21, 1884.

HORTON, S. M., *Major and Surgeon*.—Having reported at these Headquarters from leave of absence, ordered to Fort Hays, Kansas, for duty.—*S. O. 40, Par. 2, Headquarters Department of Missouri, Fort Leavenworth, Kansas*, February 20, 1884.

PATZKI, JULIUS H., *Captain and Assistant Surgeon*.—Leave of absence extended one year, on surgeon's certificate of disability, with permission to go beyond the sea.—*S. O. 43, Par. 9, A. G. O.*, February 20, 1884.

MADDOX, T. J. C., *First Lieutenant and Assistant Surgeon*.—Assigned to temporary duty at Meyer's Springs, Texas.—*Per Post Orders No. 27, Par. 1, Fort Clark, Texas*, February 13, 1884.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

A COURSE OF LECTURES ON DERMATOLOGY.

Delivered at the University of Pennsylvania during the Session of 1883–1884.

BY LOUIS A. DUHRING, M.D.,

PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY.

(Reported by Henry Wile, M.D.)

LECTURE II.

ECZEMA.

ECZEMA, popularly known as *tetter*, may be defined as an acute or chronic inflammatory, non-contagious disease of the skin, characterized at its commencement by erythema, papules, vesicles, or pustules, or a combination of these lesions, accompanied by more or less infiltration and itching, terminating either in discharge with the formation of crusts, or in desquamation. The disease shows itself in such a variety of lesions as to render the construction of a proper definition a difficult matter; the definition presented above, however, embraces the essential and characteristic lesions. The lesions may be divided into primary and secondary; among the former, erythema, vesicle, papule, and pustule, or a combination of these, may be mentioned; among the latter, crust, fissure, and scale. The disease is a protean one. The subjective symptoms are burning or itching. The course of the disease may be either acute or chronic. It is more liable to relapses than any other disease of the skin, and these may occur in any variety, and to any extent.

There are four principal varieties: eczema erythematosum, eczema vesiculosum, eczema papulosum, and eczema pustulosum.

Eczema erythematosum is a distinct inflammation of the skin, characterized by an erythematous inflammatory surface, with more or less infiltration, swelling, and itching, terminating in desquamation. In this country it is a common variety of the disease, not, as a rule, acute, but having a tendency to become chronic. It remains, generally, the same from beginning to end, and does not incline to run into other varieties. Slight moisture may, at times, be present, but the lesion, as a rule, remains dry.

Eczema vesiculosum appears in the form of pin-point to pin-head sized vesicles, usually on a red base. There is no grouping, but the vesicles tend to form variously sized patches. They appear often in successive crops, forming quickly, becoming distended with a yellowish, clear fluid, and rupturing in from twelve to forty-eight hours. The development is sometimes so fast that one is scarcely able to note the disease in the vesicular stage.

Eczema papulosum is characterized by the formation of pin-head to small split-pea sized papules, discrete, confluent, or in patches, accompanied by itching or burning. The subjective symptom of itching is usually so violent that the lesions soon become scratched and excoriated.

Eczema pustulosum exists in the form of well- or ill-defined minute or small pustules, similar in their general features to the vesicles just described. It occurs most frequently in infants, children, and young persons. The common sites are the face and scalp.

There are several important sub-varieties, the chief one being *eczema rubrum*, characterized by the multiformity of the lesions, some being primary, others secondary. This form is usually the further development of one of the foregoing varieties, and presents a typical clinical picture, consisting of thickening and infiltration, with more or less redness of the surface, oozing, crusting, and scaling. The discharge soon forms into crusts, which adhere closely and often obscure the lesions. Clinically, it is a common form of the disease, lasting usually months or years, getting better and worse from time to time. *Eczema madidans*, or weeping eczema, is seen in connection with eczema vesiculosum and eczema rubrum, and is characterized by an oozing, weeping, or discharging surface.

Eczema squamosum, or scaly eczema, is also common, and is generally chronic, lasting months. The scaling, as a rule, is scanty. *Eczema fissum*, or fissured eczema, occurs mostly about the hands and feet, especially the joints. *Eczema verrucosum* is so called from the papillary or warty condition of the lesions, and generally exists as a patch.

Eczema is also divided, respecting the pathological changes and the duration of the disease, into *acute* and *chronic*. The acute form occurs especially in children, and sometimes without treatment runs its course, ending in recovery in a few weeks. The disease, however, as a rule, inclines to become chronic. The distinction between the acute and chronic forms is based rather upon the character of the pathological changes that take place than upon the duration of the attack. In the latter form the inflammation is often of a subacute type, and is accompanied by marked secondary changes.

Eczema is everywhere the commonest disease of the skin. It constitutes about forty per cent. of all skin diseases in Philadelphia. In Boston, of 5000 cases collected by White, 2242 were cases of eczema. In New York, of 8000 cases collected by Bulkley, thirty-three per cent. were cases of eczema; and in the statistics of the American Dermatological Association, there were 6179 cases out of 16,863. The disease is found in every sphere of society, among the poor and the rich; at all periods of life from infancy to old age. It is at times hereditary, and is more common in light-haired than in dark-haired subjects. In some individuals there exists an inherent peculiarity of the constitution which predisposes to eczema. Where this tendency exists, the disease is liable to be provoked by various constitutional disturbances, such as disorders of the digestive tract, chlorosis, deficient excretion, gout, pregnancy,

nervous exhaustion, and excessive mental strain. Among the local causes, cutaneous irritants, as mercury, sulphur, croton oil, tincture of arnica, dyestuffs, poison ivy, heat, friction, perspiration, alkalies, acids, soaps, and parasites may be mentioned.

It is a marked inflammatory disease, and in the acute form the changes are generally so rapid as to render their study difficult. In the chronic form there exists a chronic inflammation which it is difficult to distinguish from that found in dermatitis. The principal seat of change is in the rete and in the papillary layer of the corium. In the papular and vesicular varieties there exist respectively a circumscribed plastic infiltration and a serous exudation in and about the papillæ, the former giving rise to papules and the latter to vesicles.

The diagnostic points are, first, infiltration, swelling, and thickening of the skin; second, exudation, which is fluid in the case of a vesicle or pustule, and plastic in the case of a papule; and third, itching, which in the vast majority of cases is a distressing symptom. Eczema may be confounded with many diseases, according to the variety which is present. In the erythematous and vesicular varieties, it may be mistaken for scarlatina, especially when the eruption has appeared universally and rapidly in one or two days; also, with erysipelas, when the eruption has appeared rapidly on the face. But in regard to both of these diseases, the presence or absence of constitutional symptoms would aid in making a diagnosis. It may be also mistaken for erythema simplex, but in this affection there is absence of itching, swelling, and œdema; also, herpes, but here the lesions are always grouped, and seldom rupture, while in eczema the vesicles burst and give rise to the formation of crusts. It may easily be mistaken for tinea favosa of the scalp; where this disease has existed for some time, pustules may form, and the picture may closely simulate chronic pustular eczema. But a microscopic examination of the crusts would render a decision. The vesicular, papular, and pustular varieties may, moreover, be confounded with scabies. This, however, is a progressive disease, growing rapidly worse from week to week, and besides, it appears at first localized between the fingers, and about the genitalia and buttocks. The presence of the burrow in scabies is, of course, a positive diagnostic point. Eczema must be distinguished from artificial inflammations, as produced by various irritants, as, for example, croton oil, mercury, arnica, turpentine, etc. In these cases the history, the form of the lesions, and the course of the disease suffice to establish the diagnosis. The diagnosis between eczema and syphilis is not, as a rule, difficult. The vesicular lesion is practically not met with in the latter, while the papular lesions are attended with less inflammation than in eczema. The pustular variety of eczema is more superficial, and the removal of the crusts does not reveal an ulcerated surface, as in syphilis, but merely an excoriation. In pemphigus vulgaris the lesions are much larger than in eczema, and occur isolated; while pemphigus foliaceus, which resembles eczema, has a peculiar history and course of development. Pemphigus, moreover, in this country is exceedingly rare.

Eczema may be mistaken for seborrhœa, especially of the face; but it must be borne in mind that seborrhœa is a sluggish affection, accompanied with hyperæmia, and not with typical inflammation. The diagnosis between eczema and psoriasis is not always easy, especially where the latter disease is not marked, and the scales are wanting. However, the history and the course of the diseases are different, psoriasis being more steady, eczema more variable. The lesions in the former are sharply circumscribed, ending abruptly; while those of the latter generally fade away into the surrounding tissue.

Ringworm, occurring about the genitalia—especially the thighs—and extending up on to the abdomen, may, at times, closely resemble eczema; but in ringworm the lesions are sharply defined, and their borders are more or less marginate. In ringworm of the scalp, short, broken-off hairs may always be found, which, examined microscopically, show the fungus.

In sycosis, as distinguished from pustular eczema, the pustules will be found to spring from the follicles, and to be perforated by the hairs.

Eczema is a curable disease. The measures employed are both constitutional and local. In some cases constitutional treatment only avails. In acute cases, say of one to three weeks' standing, excellent results follow the use of saline aperients, as magnesia, sulphate of magnesium, bitartrate of potassium, sulphate of sodium, and Rochelle salt. For children, rhubarb may be specially recommended. Diuretics are also sometimes indicated, such as the acetate of potassium, the carbonate of potassium, and liquor potassæ. Alkaline mineral waters, as Carlsbad, are also useful. Tonics, as iron, quinine and arsenic, and cod-liver oil, are also valuable. A few words as to arsenic, our most valuable remedy. It should be given with discretion; and much better results are to be obtained by the exhibition of small rather than of large doses. In the majority of cases, the best results will accrue from the use of not more than two-minim doses of Fowler's solution. The use of the remedy must be kept up for some time. In a case of chronic universal eczema, occurring in a boy eight years old (one of the most obstinate cases that ever came under our notice in the University Hospital), local measures were of no avail, and the agent that effected a cure was arsenic. In certain forms of the disease, however, as in chronic eczema of the leg, where there is thickening, it is not to be relied on; but in the chronic papular variety, and in some forms of erythematous eczema, occurring in broken-down, debilitated subjects, where the nervous system is at fault, arsenic may be used with great advantage. It is indicated, as a rule, only in chronic, never, or rarely, in acute cases.

Local treatment is important and is always demanded. The variety of the disease should be taken into consideration, also the amount of surface involved, the region, duration, and the history. In the erythematous variety, usually met with about the face, much benefit may be derived from the use of lotions of carbolic and boracic acids; the former is of particular value, and may be thus used:

℞.—Acidi carbolici, ... ℥ss.
Glycerinæ, ... gtt. xv.
Alcoholis, ... f℥j.
Aquæ, ... f℥iv.—M.
Sig.—Lotion. Apply several times a day.

The following lotion of prepared calamine and oxide of zinc is also recommended.

℞.—Calaminæ præparatæ, . . . ℥ss.
Zinci oxidi, ... ℥ss.
Glycerinæ, ... f℥ss.
Aquæ calcis, ... f℥iv.—M.
Sig.—Shake before using. Apply as a lotion three or four times a day.

Or the compound sulphide of zinc lotion, made as follows:

℞.—Zinci sulphatis,
Potassii sulphureti, . . . āā ℥ss.
Aquæ rosæ, ... f℥iv. —M.
Sig.—Apply twice a day, for ten minutes each time.

In the vesicular variety, in the acute stage, excellent results will often follow the use of black wash followed immediately by oxide of zinc ointment. Oxide of zinc ointment is a valuable, mildly stimulating, drying ointment, and is useful alone and also in combination with other remedies. Of the various dusting powders, the following is one of the best:

℞.—Talci veneti, ... ℥iv.
Zinci oxidi, ... ℥j.
Amyli, ... ℥iij.—M.
Sig.—Dusting powder. Apply freely.

Salicylic acid, ten or fifteen grains to the ounce of lard, and oleate of zinc, one drachm to the ounce, do well in some cases. The calamine lotion above referred to is also valuable in the vesicular variety.

Papular eczema, as a rule, requires strong lotions. Among the best is one of carbolic acid, as follows:

℞.—Acidi carbolici, ... ℥iss to ℥iij.
Aquæ, ... Oj.—M.
Sig.—Use as lotion several times a day.

Thymol, one to three grains to the ounce of water may also be mentioned; and liquor picis alkalinus, the formula for the latter being as follows:

℞.—Picis liquidæ, ... f℥ij.
Potassæ causticæ . . . f℥j.
Aquæ, ... f℥v.—M.

This is to be used diluted with water in the strength of one drachm to two or four ounces of water. The liquor carbonis detergens, or alcoholic solution of coal-tar, will be found serviceable.

Strong sulphur ointments are also sometimes very valuable.

In the pustular variety, ointments of calomel, white precipitate, and sulphur, from one scruple to one drachm to the ounce of lard, may be recommended. In the squamous variety, tar is the most valuable remedy, and may be used in the form of the oil of cade, one or two drachms to the ounce of lard, or in the form of the officinal tar ointment, or as the liquor picis alkalinus, mentioned above. Ammoniated mercury, fifteen to forty grains to the ounce, may also be mentioned as serviceable. Where large surfaces are involved, a remedy like tar should first be tried on a small patch, to determine whether it will agree.

In eczema rubrum of the leg, the rubber bandage may frequently be used with benefit. In concluding the subject of treatment, it may be added that there is no one remedy which can be positively relied upon to effect a cure in a given case, especially where the lesions are extensive.

ORIGINAL ARTICLES.

THE EXTERNAL THERAPEUTICS OF PULMONARY CONSUMPTION.

By THOMAS J. MAYS, M.D.,
of Upper Lehigh, Pa.

There can be no question that the beginning, the course, and the duration of pulmonary consumption are entirely limited and modified by the amount of resistance which the bodily forces are able to bring to bear in opposition to its progress. This statement is well sustained by the general well-known facts that the well-fed, the well-clothed, the well-housed, the well-developed, and the strong, possess a constant immunity from the disease; while the weak, the delicate, and the poorly nourished are constantly menaced by it, and easily fall a prey to its ravages—showing that it is a struggle between the forces inherent in the organism and those which play upon it, and that the outcome is a victory for the stronger.

Without entering here into a minute discussion of the pathology of pulmonary phthisis, or whether the immortal bacilli of Koch are a cause or a product of the disease, it may yet be safely said that both the pneumonic and tubercular forms of consumption are maladies in which the principal and most conspicuous destructive rôle is played by inflammation, either as a cause or effect. But it must not be forgotten that, while the lungs are the organs in which the most active manifestation of the disease takes place, there is no evidence to show that it is exclusively confined to these organs, and that the rest of the body does not bear a proportionate share of the disintegrating process; but, on the contrary, there is every reason to believe that the disease is constitutional as well as local; for no amount of argument can convince him who has had any thoughtful experience with the disease, that the extreme general debility, the prostration and depression of the nervous and muscular systems, the easily disturbed circulation, the shortness of breath, the clubbed finger-ends, and the hæmophilia, can be accounted for by the presence of a slight apex infiltration, or even by a partial destruction of lung-tissue—since it is too well known that there are scores of individuals who, with large portions of their pulmonary tissue excavated by previous disease, are to all intents and purposes well, and are able to perform a day's labor tolerably without much difficulty.

If, then, pulmonary consumption is a local as well as a general disease, and if its course and duration are related in inverse proportion to the amount of resistance which the bodily forces can offer to its progress, then our therapeutic line of duty lies plainly in the direction of enhancing and strengthening the forces of the body by local and constitutional means to a degree sufficient to counteract the process of disease.

In this paper I have limited myself to a discussion of the external therapeutics of pulmonary consump-

tion; not because I believe that internal medication alone in this disease is of very little permanent benefit, but because I believe that this form of treatment has never received the encouragement which it deserves, and because I think I can demonstrate by palpable evidence that its practical results are superior to any other mode of treatment yet brought before the profession. The agents which are employed are those generally known as "counter-irritants" and "massage."

I do not think that the wisdom of any person will ever be questioned if, before he undertakes to perform any kind of work, he previously endeavors to ascertain accurate knowledge of his instruments and of their actions, as well as of the material on which he expects to operate. So it is in therapeutics, if we hope to accomplish anything. We must first find out the general action of the agents which we wish to employ, as well as the general tendency of the disease which we expect to alleviate, and then, if possible, adapt the former to the latter in such a way as to obtain the desired results. I am not unmindful, however, that theorizing, especially in medicine, is under grave suspicion in some quarters, and I shall, therefore, ask permission to indulge in a discussion of the *modus operandi* of the two agents which form the basis of treatment in this paper, in the firm belief that without sound theoretical guidance our practice is blind.

The term "counter-irritant," as I have said elsewhere, is applied to various therapeutic substances, such as antimony, croton oil, cantharides, ammonia, iodine, turpentine, friction, hot poultices, etc., and is evidently out of place, for irritation is not one of their common products; and when an irritant effect is produced by them, it should never, as a rule, be transmitted to the seat of disease. It is the impulse of stimulation which they call forth, and not that of irritation, which is communicated to the cells of the body, and which invigorates and enhances their functions.

The *modus operandi* of these substances is currently believed to consist in causing accelerated action on the surface of the body, producing redness, and thus inviting the supposed superabundant blood away from the diseased organ over which they are applied. The validity of this depletory view of their action may well be questioned on the strength of various well-founded reasons, for the happy effects which we often obtain from the treatment of neuralgia by blistering, for example, cannot possibly be due to the depletion which is believed to be occasioned by the latter, for the nervous structures in nearly all cases of neuralgia are already in an anæmic state. Again, take eczema, or some other form of cutaneous inflammation; and where, let me ask, is the medical practitioner who has not witnessed a disappearance of the redness and inflammation, and a healthy color of the skin substituted under the benign influence of a poultice. Here the supposed counter-irritant is brought in direct contact with an inflamed portion of the skin; and if it were true that this agent relieves the disease by simply inviting a larger amount of blood to its immediate vicinity, then it should occur in this instance; but instead of this, the part becomes blanched and pale, and the inflammation disappears. Nor can any one reasonably expect to derive any benefit whatever from the employment of these external remedies in the treatment of pulmonary phthisis on the score of depletion, especially not after the disease has reached its second stage. For caseous masses, no matter whether resulting from the tubercular or inflammatory infiltration, are already in a semi-isolated condition, if not entirely cut off from all vascular communication, and hence disintegrate and die. The pressing indication here is provision for a more copious and abundant blood supply to nourish the famishing and fast-starving tissues, and plainly not for still greater depletion; indeed, the presence and absence of blood supply in the lungs in phthisis are important elements in the history of the disease, and must be taken into consideration in its treatment; for, it is a fact that persons suffering from mitral disease, and whose lungs are therefore in a more or less constant hyperæmic condition, rarely die from phthisis. To this aspect of the treatment I shall revert further on.

A rational inquiry for a principle which underlies the physiological action of these external remedies, will show us that they have at least one general law pervading their action, and that is an increase of molecular and cellular motion. They all conform to this law, and though they act with different intensity, their action yet differs chiefly in degree, and not in kind—in quantity, and not in quality. But it may be said that most all disease, and especially inflammation, is a process of increased molecular activity, and why prescribe an agent which tends to the same end, and thus increase the trouble instead of lessening it? We must recollect, however, that all disease is a process of disintegration, and inclines to diffuse and radiate until met and counteracted by healthy molecular motion, and that these *external stimulants*, as I shall term them in this paper, control disease, not by acting so much upon the disease centre itself, as by influencing and strengthening the more or less healthy tissues which surround the disease.

To make this clear I shall state that all motion, whether massive or molecular, takes place in the line of least resistance, and if the resistance is less on the side of health than it is on that of disease, then diseased motion will spread, *vice versa;* and if there is not sufficient force present in the body to resist and counterbalance the progress of disease, then death must follow. This resisting power varies in different individuals, and in the same individual at different periods, and it is well exemplified in the processes of mortification and gangrene. The line of demarcation, which is the battle-line between morbid and healthy action, may be fixing itself in a certain locality, and the strength of the patient, from some incidental cause, may be suddenly depressed still further, thus diminishing the resistance of the body and allowing the line to settle still closer to the centre of the body. The same conflict between healthy and diseased action is also well seen in chronic ulcers, where the line between health and disease advances and recedes, making the

ulcer appear large at one time and small at another, in direct correspondence with the strength of the patient and of the part; and it is a noted fact that the line of treatment which is pursued by all rational practitioners in these ulcers is that of endeavoring to maintain or enhance the resisting power of the patient by various means, prominent among which are the external stimulants. In threatened invasion of mortification or of gangrene, the early application of a warm poultice will often avert the danger, or at least tend to circumscribe and limit it to a smaller area than if left to its own unrestricted course. In lacerated and contused wounds, such as are usually produced by heavy machinery, there is often a disposition towards coldness, and with but little tendency to react; here the persistent application of a warm poultice will frequently restore the injured parts to a more healthy state.

Now, if the intensity of the inflammatory process were represented by a shaded line, the darkest color or shade would represent the centre of inflammation —the seat of greatest activity; next would be a shaded circle of lighter color; the next circle would be a shade lighter, and so on, until finally the color would fade into the light hue of health. It is evident, therefore, that there are many grades of activity between health and disease; that the former fades imperceptibly into the latter, and the latter imperceptibly into the former; and that there are grades which are neither constantly the one nor the other, but oscillate between the two. So from all the data which have been embodied in this paper thus far, I think it will appear obvious that through the agency of these *external stimulants* we can shift the battle-line between health and disease; or, in other words, that we can through them not only deflect disease and diffuse healthy action into regions which were previously invaded by disease, by enhancing molecular and cellular activity in the surroundings of inflammatory action, but also remove the products of inflammatory action, and so prevent the spread of disease and also eradicate it.

Care must be exercised in the selection of the proper stimulant, for it is a very easy matter to generate more excitement on the surface than is necessary, and thus aggravate rather than benefit the disease. This appertains especially to the different forms of inflammation. As a rule, the more recent the disease, other things equal, the easier it is influenced and its progress checked; hence, the milder external stimulants, such as mustard, turpentine, ammonia, friction, poultices, etc., must be applied; but in the well-settled or chronic form, the most active measures, such as blisters, croton oil, and other agents are indicated.

From a considerable experience in the treatment of chronic lung troubles, I became convinced some time ago that none of the external stimulants then in current use were sufficiently powerful to modify or ameliorate the more chronic and persistent hereditary forms of pulmonary phthisis, and I have designed a rubber apparatus[1] for the chest in the shape of a double jacket, into which steam is forced through rubber tubing from a boiler on a neighboring stove. I partly failed in my object then, because the rubber yielded too readily to the disintegrating effects of steam; but the clinical results which I obtained from its limited use satisfied me that further efforts in seeking suitable material for the construction of such an apparatus would be well worth a trial. So I had lately made, by Messrs. Tiemann & Co., of New York, a steam-jacket of tin metal, which, from a somewhat protracted use, seems to fulfil all the ends I had originally in view. The inside surface of the jacket is covered by a lining, an inch in thickness, composed of cotton wadding, covered with several thicknesses of flannel. This lining is moistened with water and heated before the jacket is adjusted to the chest. Thus arranged, it will be observed that it strictly fills all the requirements of a strong and powerful external stimulant, and, while its action is the same in kind to that of a hot flaxseed poultice, only a great deal stronger, it possesses many prominent advantages over ordinary poultices and other appliances previously employed. It envelops the whole chest completely. It is light and readily adjusted. It retains its position on the chest without difficulty. It is easily managed and operated. It maintains a constant and uniform temperature. It requires no renewal every hour.

The patients are allowed to remain in the steam-jacket for a varying period, from two to five hours each day. The steaming, besides causing an intense thirst, also calls forth a copious perspiration, and, as a precautionary measure against a too sudden change in the bodily temperature, the patients are advised to dress dry and go to bed, cover up well immediately after the jacket is taken off, and to remain there until sufficiently cooled off. The thirst is so great that a patient frequently drinks from two to three quarts of milk, or of milk and water, during three hours' steaming. Whether the moisture which is applied externally to the body under such a high temperature is absorbed by the circulation, is rendered probable by physiological experiment; but it is certain that the large amount of liquid which patients take by the mouth cannot fail to promote molecular and cellular metamorphosis in the tissues of the lungs, surrounding the centres of disease, under the intense stimulation which is superinduced by the steam-jacket.

Last winter, I witnessed a series of very interesting experiments on the physiological effects of massage, which were made by Dr. Zabludowski, under the direction of my friend and teacher, Prof. Kronecker, in the Physiological Laboratory of the Berlin University, where I was engaged in physiological work at the same time. The results of his experiments, which were since published in the *Centralblatt für die medizinischen Wissenschaften*, No. 14, convinced me that massage had a tonic and invigorating influence upon the animal body; and during my attendance, last spring, at the Brompton Hospital for Consumption, in London, I related the result of those experiments to Dr. Bruce, of the hospital staff, and he concurred with me in the belief that bodily massage, by arousing the consti-

[1] See New York Medical Journal, October, 1879.

tutional lethargy present in phthisis, might probably be a valuable adjunct in its treatment. Since my return, I have had opportunities to test the efficacy of massage in a clinical way, and, while it is inferior in its beneficial effects to the steam-jacket, it has certainly proved itself to be a most useful addition to the external therapeutics of pulmonary consumption.

The following is a condensed record of the cases which have been treated by this form of external stimulation and massage. Although most of the cases have been under daily observation, and a careful record of the temperature, symptoms, and physical signs was kept in all cases but one, in which it was impossible to obtain accurate temperature observation, on account of the unlettered condition of the patient and his family, I shall only relate the most salient points in their history and progress. Case I. was treated by the rubber jacket alone. Case II. was first treated with poultices, etc., and finally by the rubber jacket. Case III. by poultices alone. Cases IV., V., and VI. by poultices and massage. Cases VII. and VIII. by poultices and massage for a while unsuccessfully, and then with tin steam-jacket alone. Case IX. by steam-jacket alone. It is but fair to state that, while the external treatment was in progress, nearly all the patients took cod-liver oil, and all of them meat-juice, milk, and the most nutritious diet they could afford. Tubercle bacilli were found in Cases IV., V., VI., VII., and IX.

CASE I.—D., aged eighteen years, became my patient on May 6, 1879. Coughed since previous August; had a copious expectoration, first green, then streaked with blood; had hæmoptysis two months before; also subject to chills and night-sweats; lost in flesh; appetite poor; bowels and menses regular; and had clubbed finger-ends. No trace of hereditary disease in family history.

Physical Signs.—Diminished resonance over whole of left lung; crepitation at apex, and rough respiratory sound towards the base. Right side normal.

Treatment.—Applied the original rubber steam-jacket on May 8, and she used it almost daily until June 17. Under its action she improved in cough, expectoration, chills, night-sweats, appetite, etc., and on the day the steaming was discontinued the physical examination showed that the diminished resonance and crepitation had vanished, and were replaced by a rather harsh vesicular murmur. When last heard from, about a year ago, she was doing well. This case, in the rapid amelioration of the physical signs, is analogous to Case IV.

CASE II.—S., married, aged forty-five, came under my care, March, 1879, in the following condition: Sleeps poorly, coughs constantly, expectorates profusely, color of which is yellowish-gray; has night-sweats, chills, poor appetite, coated tongue; bowels irregular, and is losing flesh. One brother died of consumption; rest of his family exempt from phthisis.

Physical Signs.—Left side: dulness, crepitation and bronchial respiration in upper two-thirds, crepitation specially audible in middle third behind. Right side normal.

Treatment.—Until May 21, 1879, he was treated with poultices, cod-liver oil, etc., with little or no success, and from this time on to June 25 he used the rubber steam-jacket. Under this form of stimulation his cough, expectoration, chills, and night-sweats, gradually diminished, his appetite and sleep returned, and on June 26 the steaming was discontinued, and a physical examination showed that the dulness and crepitation were replaced by a somewhat harsh vesicular murmur in the upper third of left lung, and a cavity of the size of an egg in the middle third behind. At present writing (February 4, 1884), the cavity is somewhat shrunken, and he still has a cough, but is strong and fleshy, and well able to work every day.

CASE III.—K., aged nineteen, single, I first saw November 24, 1880. Coughed for a month, had yellow expectoration streaked with blood, stitches in left apex, night-sweats, lost flesh, poor appetite, vomited his food, and had clubbed finger-ends. Lost a brother the previous year, probably with phthisis.

Physical Signs.—Left side: diminished resonance, crepitation and wavy respiration from apex to third rib. Puerile respiration over remainder of lung. Right side normal.

Treatment.—Flaxseed poultices over left shoulder, meat-juice, cod-liver oil, and nourishing food as well as some hypophosphite of lime.

January 10.—Feels good, and physical signs as well as symptoms markedly improved; poultices discontinued. He then moved out of my field, but from last accounts (October 13, 1883), he was well and got married some time before.

CASE IV.—D., single, aged twenty, I began to treat July 19, 1883. She had a cough for a year, chills, lost flesh, poor appetite, and sleeplessness, never expectorated blood. Weight 100½ pounds. Her father's mother and sister, and her mother's sister died of consumption. She lost a brother at the age of eighteen from some form of lung trouble.

Physical Signs.—Dulness over left apex, chiefly over its posterior aspect, and crepitation over same region. Right side normal.

Treatment.—Flaxseed poultices over upper portion of left lung, and massage of the whole body twice a day.

September 7.—Dulness over left apex almost entirely gone, no crepitation anywhere, and is replaced by a weak, but otherwise normal, respiratory sound. Her symptoms are also very much improved. She weighs 109 pounds. Discontinued poultices and substituted iodine ointment. When last heard from (last December), she was doing well.

CASE V.—P., aged four and a half years, came in my hands in the beginning of last July, when he was suffering from catarrhal-pneumonic phthisis of the left lung. Cavity-formation was then going on in apex, cavernous râles in middle, and complete dulness and absence of respiratory sound in lower third of left lung, anteriorly, posteriorly, and laterally. Right lung normal, except hyper-resonant. Tubercle bacilli were found in large numbers. Weight of patient, 30½ pounds. A brother of the boy's father died from phthisis about ten years before.

Treatment.—Flaxseed poultices and two bodily massages every day.

July 19.—Same treatment. Mucous râles found on right side posteriorly, extending from apex along spine to base. Left side about the same as at last examination, although the patient seemed better in some respects.

August 8.—He suddenly spat up about half a pint of yellow, purulent fluid, which evidently came from an abscess in left lung, towards its base, where the absolute dulness existed, for a physical examination disclosed an extension of the cavity. Mucous or moist râles persist at base of right lung; none any longer at apex.

18th.—Same treatment. Moist râles at base gone.

24th.—Very few tubercle bacilli found in sputum. Discontinued poultices and massage, and applied iodine ointment to chest.

Physical Signs (26th).—Left side, cavity extending from first to sixth rib, anteriorly, and posteriorly to angle of scapula. Considerable retraction at apex. Very few moist râles at base; otherwise, respiratory sound is restored, though diminished in force. Right side normal, except hyper-resonant. Weight, 35 pounds. December 13, doing well. Weight, 40 pounds. At present doing well.

CASE VI.—August 4, 1883. G., married three years; aged twenty-eight years, and mother of two children. Has had a cough since she had measles, when three years old; cough aggravated since she married, and she became very much worse after both her confinements. Had copious hæmoptysis last March, losing about one quart of blood, and has lost flesh rapidly ever since. Present weight, 102½ pounds; a week ago, she weighed half a pound more. No family history of consumption on either her father or her mother's side. Her brothers and sisters are all well.

Physical Signs. — Right side depressed and sunken from clavicle to mammary region; tympanitic sound over this region; cavernous râles at base. Left side resonant on percussion over the whole extent; coarse mucous râles posteriorly at base and interscapular region.

Treatment.—Flaxseed poultices over whole chest, massage twice a day, cod-liver oil and meat-juice. After a week's treatment she began to mend, and on September 27 the poultices and massage were discontinued. She was very much improved in every respect, and presented the following physical signs: Right side: small cavity at base anteriorly, no râles anywhere. Left side: few bronchial râles at base, and cavity in interscapular region. She sleeps well, coughs very little, her expectoration now is mucous instead of greenish-gray; has good appetite, and weighs 111½ pounds.

December 7.—Still doing well; her cough persists in a mild form, and she weighs 114 pounds.

30th.—Is able to do her own housework.

CASE VII.—I began to attend B., aged thirty, married, on September 30, 1883. Has been ill since last June, when he was taken with a severe chill. Coughs a great deal; has a green expectoration, night-sweats, loses flesh, poor appetite, irregular bowels, clubbed finger-ends; frequently spits blood, and to-day he had a very profuse hemorrhage from his lungs—probably lost over one pint of blood. Lost one brother from consumption.

Physical Signs.—Left side: Tympanitic sound over apex, extending to angle of scapula behind, and in front to third rib, with slight dulness extending for a few inches below these points; cavernous sounds from apex to third rib in front, and to angle of scapula behind, with some moist and crepitant sounds below this; base normal. Right side: Respiratory sounds normal, except prolongation of expiratory sound at apex. Weight, 133 pounds. Tubercle bacilli abundant.

Treatment.—Flaxseed poultices over whole chest, and massage twice a day; meat-juice, milk, cod-liver oil, and a nutritious diet. He began to improve, not only in his symptoms, but the physical signs also mended considerably.

On October 21st there were very few moist râles audible anywhere in his whole chest; but on October 22d another examination showed that tubular breathing and moist râles were developing themselves in lower half of left lung behind. On October 24th ceased to poultice, and applied croton-oil liniment over whole chest and continued massage. I now made arrangements with Messrs. Tiemann & Co. to construct a tin-metal steam-jacket for him. On account of several unavoidable delays in the manufacture of the jacket, I did not get it until November 20th, when the disease had also extended to the right apex, and formed a small cavity there. The physical signs at this time were the following. Left side, anterior: Cavity extending to fourth rib, tubular breathing and moist râles from here to base. Posterior: Cavity to angle of scapula; from here to base, tubular breathing and some moist râles. Right side, anterior: Small cavity extending to right intercostal space, below this normal. Posterior: Cavity small in apex; rough breathing at angle of scapula, below this to base some moist, but chiefly normal, sounds. I now omitted the massage, and began the use of the steam-jacket. He began to improve, as was well shown by the amelioration in his symptoms and physical condition. On January 18, 1884, I took off the steam-jacket. He had very little cough and expectoration; no chills nor night-sweats, and presented the following physical signs. Left side, anterior: No moist râles; base clear also laterally. Posterior: No moist sounds except a few clicks over cavity; respiratory sounds normal from cavity to base. Right side: Normal over whole lung except small cavity in apex.

Feb. 1.—Very few tubercle bacilli in sputum. It is unnecessary to point out that the condition of this patient was well-nigh desperate when the steam-jacket was applied, and whether he will fully recover his health (although at present writing he is still improving weighs 136½ pounds) the future alone can determine. The results in this case are certainly very interesting, when we reflect that the whole course of treatment was carried out under the most unfavorable hygienic surroundings—in one room, where most of the cooking, the heating, the eating, and most of the sleeping of a family of seven

members were done; and that during a most rigorous winter. His temperature, which ranged from 100½° in the morning to 103° in the evening, when I first took him in charge, has seldom varied more during the past month than from 98½° in the morning to 99½° in the evening.

CASE VIII.—K., aged forty, married, came under my care August 1, 1883. Received an injury to his left side about seven months before, which resulted in pleuro-pneumonia of the left lung. He coughed a great deal; expectoration dark-green and streaked with blood; never had hæmoptysis; no night-sweats nor chills; very little variation in temperature then; hoarseness and pain over larynx; good appetite; bowels regular, but somewhat inclined to diarrhœa. No trace of consumption in family history. No tubercle bacilli found. Weight, 128¾ pounds.

Physical Signs.—Left side: tympanitic resonance from apex to nipple, and absolute dulness from here to base, also absolute dulness behind and laterally at base. Cavernous sounds from apex to nipple; complete absence of respiratory sounds or râles from here to base; the same absent behind and laterally. Right chest normal.

Treatment.—Flaxseed poultices and massage, cod-liver oil and nutritious diet. He steadily improved under this treatment in all his symptoms and physical signs, until August 29th, when he weighed 135½ pounds. After this the poultice and massage lost their influence over the disease, and there was little or no progress in his case for several weeks, after which he gradually lost ground. The poultice and massage were stopped, and on December 9th the steam-jacket was applied. His weight at this time had sunk to 133½ pounds, and his physical condition was as follows: Left lung about same as at first examination, except large cavity in apex. Right lung, no dulness or impaired resonance anywhere; wavy respiration in upper third anteriorly, and broncho-vesicular respiration at base, posteriorly and laterally. Massage and cod-liver oil were discontinued. From this time he began to improve again in his physical condition, symptoms, and feelings. On December 14th he said that since he is steaming, he feels "quite like another man." On December 26th the physical signs noted are—left side: dulness from cavity to base markedly diminished, and moist râles heard here where there was complete suppression of all sounds before. Right side about the same.

Jan. 4.—The physical signs are about the same as at last examination, except that to the broncho-vesicular respiration at base of right lung are added a few moist and sibilant râles.

12th.—The physical signs were as follows: Left side: moist râles towards base diminishing, and are replaced by more normal respiratory sounds, sunken over upper third. Right side: wavy respiration still present, though improving; moist and sibilant râles have disappeared at base.

Feb. 4th.—The physical signs are: Left: moist râles below cavity less intense and less numerous; respiratory sounds now plainly perceived over whole lung below cavity. Right side: free from all moist and sibilant râles at base; wavy respiration in apex improving. Weight has not been taken since he began steaming.

He is still under treatment.

CASE IX.—Was asked to see W., married, aged forty-six, on January 18, 1884, who was well up to within one year ago, when he was taken with a cough and hæmoptysis. Had another hemorrhage three weeks before I saw him. Has now a constant cough, feels chilly, has night-sweats and sleeplessness, poor appetite, vomits after every meal, bowels regular, clubbed finger-ends. No evidence of consumption in family history. Abundance of tubercle bacilli in sputum.

Physical Signs.—Right side: Impaired percussion resonance anterior to nipple, and posteriorly to about two inches of angle of scapula, crepitation extending over this same region. Left side: Hyper-resonant and normal, though increased respiratory sound.

Treatment.—Steam-jacket and nutritious diet, as well as cod-liver oil.

February 4.—His symptoms are: Sleeps well; coughs and expectorates very little; has no chills or night-sweats; appetite medium; bowels costive; has not vomited since he began steaming, and says his general strength is improving. His physical signs are as follows: Right side: Percussion resonance in upper portion of lung about the same, although there is less marked crepitation in this region—only audible as far as the third rib anteriorly, and to the spine of the scapula posteriorly. Still under treatment.

The result of these cases might have been withheld from the medical public for a year or two longer for the purpose of observing the future development in the last three cases; but when we come to consider that in no single instance where this method of treatment has had a fair trial did it fail in a disease which is notoriously rebellious to treatment; that the complete recovery of the first three cases is placed beyond a doubt by the time which has elapsed since their treatment; and that in the last three cases the improvement and the amelioration in their symptoms and physical signs were just as decided as in the first three, I think I feel justified in their publication.

UPPER LEHIGH, PA., February 4, 1884.

BURQISM, OR METALLOTHERAPY IN THE TREATMENT OF OCULAR AFFECTIONS—HYPERÆSTHESIA OF THE RETINA.

BY ARTHUR JOHNSTONE, M.D.,
OF PHILADELPHIA,
AND
L. WEBSTER FOX, M.D.,
LATE HOUSE SURGEON AND CLINICAL ASSISTANT TO THE ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS; OPHTHALMIC AND AURAL SURGEON TO THE GERMANTOWN HOSPITAL; CLINICAL ASSISTANT TO THE EYE DEPARTMENT OF JEFFERSON MEDICAL COLLEGE HOSPITAL, ETC.

WE here beg to present the first of a series of cases, all treated by this method, as applicable in eye affections complicated with neurotic symptoms,

local and general. The whole series will include such cases as present themselves in daily practice, and will represent the results obtained in every case, whether successful or not. We likewise wish to mention that they are all chronic cases, most of them having undergone a variety of treatment, including correction of visual defect by glasses, without any relief however.

It will be observed that in the following article we have occasion to mention a symptom concomitant with hyperæsthesia of the retina, which we designate as *temporal reflex*. As attention has not been called to this symptom by previous writers, we shall briefly describe it, reserving for a future article its full significance in certain ocular troubles. This reflex phenomenon is elicited by gently stroking the temple with the finger from the ear towards the outer canthus of the eye. In a few patients, a small sensitive spot, about one centimetre in diameter, is found on the forehead just above the eyebrow; again, immediately below the lower eyelid. Patients describe the sensation arising from this as if they were slightly pricked by needles. It is a symptom found in hyperæsthesia of the retina, retinitis, asthenopia, sympathetic ocular troubles, and is accompanied at times with venous fulness and swollen eyelids.

Case I. *Hyperæsthesia of retina; temporal reflex; sensibility—steel; cured.*—C. H. F., æt. 35; engineer U. S. N.; married.

Three years ago, after a great deal of mental strain and use of his eyes in rendering his accounts to the Navy Department, he began to experience great pain in and around the eyes when exposed to artificial or sunlight. Gradually this symptom became so distressing that the patient became unable to take exercise during the day, and was only able to do so after dark, and then he had to avoid gaslights in the windows and streets.

For this condition he consulted various oculists (ten), both in New York and Philadelphia. He was given glasses for his manifest hypermetropia, and at the hands of several he went through thorough and varied courses of medication. His condition went on, from bad to worse, till November 21, 1883, when we first saw him. His condition was then as follows: General health very much below par; careful examination of thoracic and abdominal organs elicited nothing of importance. The condition of the eyes was as follows: Complete intolerance of light for more than a few seconds, which would always give rise to headache, pain in the temples shooting down the back of the neck, along the arms, and sometimes over the pectoral region. There were likewise excessive flow of tears and blepharospasm. Ophthalmoscopic examination was difficult, owing to the dread of light.

By great effort and self-control on the part of the patient, the fundus oculi was explored. Conjunctivæ hyperæmic; corneæ clear; anterior chambers shallow; pupils contracted, but responsive to light; retinæ slightly reddened; arteries and veins normal in calibre; optic disks with their sheaths well defined; choroids slightly pigmented.

Vision, right eye, $\frac{20}{XX}$; J. $\frac{1}{8''}$.

Vision, left eye, $\frac{20}{XX}$; J. $\frac{1}{8''}$.

Only for a few seconds could the patient hold his vision. His manifest hypermetropia was about sph. 0.75 D. The ophthalmoscope revealed 1.75 D. of hypermetropia, slightly less in the left eye. He was ordered a solution of atropia gr. iv to f℥j, one drop to each eye thrice daily, to arrest the accommodation, to ascertain accurately the dioptric defect. This treatment was continued for four days, when his visual acuity was as follows:

Right eye, $\frac{20}{L}$; $\frac{\quad}{C}$; sph. + 1.75 D. = $\frac{20}{XX}$.

Left eye, $\frac{20}{L}$; $\frac{\quad}{C}$; sph. + 1.50 D. = $\frac{20}{XX}$.

A later examination confirmed the above record, and the full correction prescribed for constant use. Although these glasses were constantly worn, and outdoor exercise attended to as far as the patient's condition would admit, the photophobia and neuralgic symptoms remained unchanged. Considering the varied medication he had had without benefit, we concluded as a last resort to give him a trial with metallotherapy, of the success of which in apparently hopeless cases we had been eye-witnesses during our stay in Paris, under the direction of our illustrious preceptor, Dr. Burq. After repeated trials, the patient was found sensitive to *steel*, which was consequently ordered him in the form of tinct. ferri. chlor., ten drops three times daily.

Nov. 26.—Dynamometer: Right hand, 42 kilos; left hand, 36 kilos. Sleeps well all night through, which was not the case formerly; appetite improved; bowels free and regular, formerly constipated; distant vision improved; temporal reflex less exaggerated; retina more tolerant of light, but when by accident unduly excited, untoward symptoms now pass off, and a more normal condition is established in a shorter space of time.

From the above date to the present writing (January 29), the patient has kept steadily improving, till now he can read a column of finely printed matter of a daily newspaper; artificial and sunlight borne without inconvenience, which in itself is of great advantage to the patient, as he can now take outdoor exercise during the day; general condition much improved; appetite good; bowels regular; radiation of body-heat good, showing active capillary circulation. Dynamometer: Right hand, 44½ kilos; left hand, 39½ kilos. We may add, that during this interval the medicine was discontinued for one week, at the end of which time the temporal reflex became manifest, with slight intolerance to light. The drug was again given, when symptoms disappeared. At present he is not under treatment.

Case II. *Hyperæsthesia of retina; temporal reflex; general neurasthenia; sensibility—gold; discharged cured.*—Miss B., æt. 25; family history irrelevant; gave the following history: Since the age of fourteen has had periorbital pain in left eye,

also extending down track of infraorbital nerve. Asthenopia, headaches, and dimness of vision; skin of an unhealthy and earthy hue; radiation of body-heat *nil;* always has cold, clammy hands and feet; sleep fails to refresh, arises tired and exhausted in the morning, has unpleasant dreams and at times nightmare; tongue coated and flabby; breath fetid; bowels obstinately constipated—at times, no passage for two weeks. Ovarian pain in left side, with very scanty menstruation, lasting on an average two days, requiring but one napkin daily; urine variable in quantity, sometimes pale and abundant, then again scanty and high-colored.

Vision, right eye, $\frac{20}{LXX}$; J. $\frac{5}{8}$"?

Vision, left eye, $\frac{10}{CC}$? *nil.*

In the right eye the ophthalmoscope revealed no lesion other than a small spot of choroiditis in the lower and outer quadrant near the periphery of fundus. The refraction was hypermetropic. The left eye had a marked pathological change. In the macular region was the evidence of an old attack of choroiditis. The area invaded was about four disk-breadths; well-marked deposits of pigment to the periphery of the spot, while several atrophied spots were visible in the centre. There was no lesion elsewhere. The arteries and veins normal in calibre, and optic nerve with its sheath well defined. Peripheral vision good. The refraction hypermetropic.

The patient was refracted under atropia, when a spherical glass + 2 D. was found to give the patient vision of $\frac{20}{XL}$ in right eye; in left eye no improvement with glasses. Dynamometer: Right hand, 26½ kilos; left hand, 20 kilos. Tactile sensibility: Points of æsthesiometer felt at a distance of four centimetres on right forearm; on left forearm, barely distinguishable at a distance of twenty centimetres. Anæsthesia extending over left side of body. The glasses giving the best vision were prescribed. Notwithstanding this, and the usual treatment adopted in such cases to alleviate the hyperæsthesia of retina, the patient's condition was only partially relieved. Encouraged by the success of our first case, we again bethought ourselves of metallotherapy. After repeated and laborious examination, her sensibility was found to be for gold. On December 15th, we instituted the treatment by gold, *inter et extra*, as follows: Tinct. auri chlor. gr. $\frac{1}{75}$, three times daily; externally to temporal region, left arm, and leg, Burq's disks. The improvement in her eyes, less sensible to light, became manifest after the second day, and general health improved until January 10, 1884, when the following notes were made of the case:

Hyperæsthesia of retina, disappeared; temporal reflex, gone; distant vision good $\left(\frac{20}{XL} +\right)$; headache but once last week; breath much purer; tongue clean; appetite good; digestion ditto. At times, slight gastralgic pains, which are attributed to the gold, as this drug is very trying to the stomach; constipation not much relieved as yet; menstruated several days ago without pain or premonition of any kind; feels in better spirits, and is able to bear fatigue well to the extent of walking two miles without any subsequent feeling of exhaustion; sleeps well at night, and feels refreshed upon rising in the morning. Muscular strength as per dynamometer: Right hand, 31 kilos; left hand, 30 kilos. Points of æsthesiometer felt at two centimetres; now more distinctly on left arm, which had previously been insensible.

Jan. 28, 1884.—Dynamometer: Right hand, 32½ kilos; left hand, 31½ kilos. Æsthesiometer, normal; no ocular trouble; detected a small sensitive spot (temporal reflex) on right temple, about size of a split pea, several days ago, after exposure to reflected sunlight while sleighing; disappeared after a few hours' rest. General condition excellent; functions normal. Treatment discontinued.

CASE III. *Hyperæsthesia of retina; general neurasthenia; sensibility—steel.*—Miss H., æt. 21, family history good.

Nov. 22, 1883.—Vision, both eyes, $\frac{20}{XX}$; J. $\frac{1}{8}$",

but fails to read for any length of time on account of pain produced, and near vision becomes blurred; headaches, and at times pain over brow, with slight temporal reflex; no lesion in fundus oculi; hypermetropia two dioptrics; full correction given for near work.

About two years ago, during a menstrual period, after exposure to wet and cold, her catamenial flow stopped. From this time she has been troubled with the following general symptoms: Ovarian pain, left side, unbearable in erect position; leucorrhœal discharge with scanty menstruation, which is always preceded and accompanied by great distress; easily fatigued, so that she can hardly attend to her household duties; bowels irregular and constipated; extremities cold, with occasional sensations of heat.

On first trial she was found sensitive to steel, which was then and there prescribed.

24th.—Patient feels much better than she has done for weeks.

26th.—General condition still continues to improve. Steel (tinct. ferri. chlor. gtt. x, three times daily), instead of constipating, relaxes bowels, producing two daily evacuations. Appetite markedly increased, so much so that patient supplements her usual three meals with a fourth; tongue quite clean. Menstruated on the 27th and 28th, without pain, and double the usual quantity of blood; scarcely any leucorrhœal discharge after menstrual period.

From November 29th to December 23d, the patient has kept constantly improving in every respect. On December 23d she again had her menstrual period; flow considerably augmented; no pain whatever, and hardly a trace of leucorrhœa, which ceased two days afterwards, and has not been noticed since. Treatment discontinued.

Jan. 29, 1884—Patient is well and able to attend to her household duties, without any sensation of fatigue, although she is on her feet during the entire day. There has been great gain of flesh. She uses the glasses for near-work, but can do without them for a longer space of time than prior to her gain of muscular tonus. The cure has been complete in every respect.

Dr. Burq's armatures, dynamometer, and æsthesiometer were used in the cases reported.

Remarks.—The noticeable features in Case I. are the duration of the symptoms therein, completely incapacitating the patient for all active duties; the rebelliousness to all ordinary treatment, including correction of visual defect by glasses; the secondary effects they entailed, namely, anæmia, indigestion, and universal derangement of functions, due to confinement; but more noticeable still, the rapid effect of the metal appropriate to the patient's idiosyncrasy.

We especially call attention to the disappearance of the retinal hyperæsthesia, wherein are included the by-symptoms of æsthenopia and photophobia, generally so intractable, and a restoration from a chronic state of invalidism to good health.

Case II. is no less remarkable for the rapid subsidence of distressing symptoms of long standing, and the restoration of all the functions to a nearly normal standard, by the metal alone appropriate to the idiocyncrasia.

Case III. again illustrates the value of metallotherapy; the drug appropriate, once found, caused the cessation of the ovarian pain and leucorrhœal discharge without local treatment whatever. It is unnecessary more than to mention the great improvement in her general health, and the complete relief of her headaches and asthenopia, in which, however, the visual correction has its share, and the menstrual molimen more than doubled. In this case we claim for the metal the result obtained, for local applications had been used without relief.

1306 Walnut Street.

ON CERTAIN UNTOWARD EFFECTS FOLLOWING THE ADMINISTRATION OF TURPETH MINERAL.

By N. A. RANDOLPH, M.D.,

ASSISTANT DEMONSTRATOR OF PHYSIOLOGY, UNIVERSITY OF PENNSYLVANIA; INSTRUCTOR IN PHYSIOLOGY, TOWNE SCIENTIFIC SCHOOL.

AND A. E. ROUSSEL, M.D.

RESIDENT PHYSICIAN AT THE PHILADELPHIA HOSPITAL; FORMERLY RESIDENT AT THE ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

We have recently had under our personal observation five cases in which the administration of turpeth mineral was followed by unexpected symptoms.

On the occasion in question, each of eight well-nourished men, in average health, was given five grains of turpeth mineral,[1] and as emesis did not follow within half an hour, three grains additional were given, with the result of inducing vomiting, more or less copious, within twenty minutes after the administration of the second dose. Beyond a continuation of the retching for some time, and a general complaint of a sense of burning in the throat and fauces, nothing unusual was observed at the time, and but little depression immediately followed the emesis.

On the following morning, however, our attention was called to the condition of five out of the eight men above mentioned. A rather violent diarrhœa had followed in from ten to twenty hours after the administration of the drug, attended by much griping and a rather unusual amount of constitutional depression. Each of these five men had passed in the twenty-four hours succeeding the exhibition of the drug, from eight to fifteen stools. These stools at first resembled those of calomel, but eventually became yellow. Appropriate treatment was administered, and on the following day the diarrhœa was partially or wholly checked, and the cases progressed favorably to recovery. It is worthy of note that in each case, the first few stools contained minute particles of the yellow sulphate, showing that not only had its elimination by emesis been far from complete, but also that the drug had been for from ten to twenty hours in contact with the tissues and fluids of the digestive tract.

In the fifth case, John H., a German, æt. 38, complained of a soreness of his gums, and of the large amount of saliva dribbling from his mouth. He had, up to this time, received no preparation of mercury for several months. An examination showed the gums to be soft and spongy, with the teeth partially loosened, the tongue swollen, covered with a thick, yellowish coat, and showing distinctly the imprint of each tooth. This, together with the large amount of saliva secreted, and the characteristic fetor of the breath, proved it to be a well-marked case of salivation, such as is fortunately rarely witnessed at the present day, either in hospital or general practice. Under appropriate treatment, however, the man improved, and was ultimately cured.

Had the cases been younger, or less vigorous, a different termination might have resulted.

At the time we regarded these results as peculiar, but shortly afterwards our attention was called to an article by Dr. McPhedran,[1] in which was given a detailed account of two fatal cases occurring in children, in which, however, emesis failed to result, as also a similar case in the *Medical and Surgical Reporter*.[2]

Upon examining the literature of the subject we find that Dr. Hubbard, of Maine, was among the first to use this drug, but to Dr. Fordyce Barker, of New York, belongs the credit of bringing it prominently before the attention of the profession. In an article on "Croup,"[3] Dr. Barker states that after an experience of twenty years, he considers turpeth mineral the best emetic for use in this disease, and goes so far as to recommend that it be kept on hand

[1] The drug was purchased from a reliable wholesale dealer in this city.

[2] January 19, 1884, p. 93.
[3] American Journal of Obstetrics, May, 1870.

in all families with children of a croupy tendency, administered at the earliest symptoms of an attack, and before sending for a physician.

Abroad, also, the drug seems to have been received with favor. Drs. Desmartis and de Titray,[1] who consider the membrane in croup as due to the result of blood-poisoning of a fermentative character, advocate the merits of the remedy as twofold, viz., as exerting a specific agency upon the ferment, and also as removing the deposits by emesis. They record its use in a number of cases, of different ages, with good results.

Again, Dr. Smith,[2] in his work on *Diseases of Children*, speaks of this drug in connection with croup, and mentions it as probably the best emetic in ordinary cases of this disease.

Prof. Alfred Stillé[3] quotes two cases occurring in adults with fatal results. In one, a boy, aged sixteen, took about a drachm of the drug; symptoms of the ingestion of an irritant poison followed, together with great salivation, and death ensued in a week's time.[4]

"In the second case, a man, æt. 27, took forty grains of this medicine by mistake for Æthiops mineral. The primary symptoms were precisely the same as in the above case just related. Death occurred at the end of ten days. The inner surface of the mouth, gums, palate, and fauces were covered with black sloughs; the parotid and submaxillary glands were enlarged; the mucous membrane throughout the intestinal canal was softened and easily torn; the glands of the stomach and intestines unnaturally large; the kidneys were much enlarged and the bladder full of urine."

A case of poisoning, with recovery, by the same drug, in a dose of "less than a drachm," is reported by Yowndes.[6]

In the *United States Dispensatory*[7] we find it stated that the drug in question operates with great promptitude, but sometimes excites salivation.

As seen by the references above given, our cases present little of novelty, excepting that the dose we used was quite within therapeutic limits, as ordinarily given; but we deem it our duty to call attention to the danger attending the administration of this drug, especially as its poisonous properties seem to have been overlooked by several recent writers on therapeutics.

Prof. Bartholow,[8] it is true, states that "serious results might be produced if emesis did not so promptly follow," which seems to agree with the experience of Dr. McPhedran already mentioned. In the cases under our own observation, however, the poisonous symptoms followed, notwithstanding that fairly copious emesis resulted in every case. The time which elapsed between exhibition and emesis (thirty-five to fifty minutes) was possibly sufficient to permit the occurrence of chemical changes in the drug as it lay in the stomach, and the minimum time of ten hours elapsing between the ingestion of the drug and its final elimination with the feces was (in one case at least) fully sufficient to account for the resultant symptoms, which were of a character tending to substantiate the statement of Miahle, that all mercurial preparations are absorbed in the form of chlorides.[1]

We are informed by several prominent dealers in drugs that the demand for turpeth mineral is quite large, and is apparently growing. This fact, together with the praise it has received in several quarters, justifies us in emphasizing the following conclusions, based upon the observations, old and new, which are given above:

1. That a dangerous quantity of turpeth mineral often remains in the stomach after emesis.

2. That this drug possesses sufficient toxic and irritant properties, not only to demand from the profession much more than usual caution in its administration, but to condemn its use where the exhibition of any other emetic is practicable.

3. That it should not be placed in the hands of the laity.

MEDICAL PROGRESS.

THE TUBERCLE BACILLUS.—In a recent paper on "The Diagnostic and Prognostic Value of the Tubercle Bacillus," DR. G. H. MACKENZIE draws the following conclusions:

1. The bacillus of tubercle is pathognomonic of tubercular disease; found in the sputum it indicates that active tubercular disease is in progress in the lungs, in the larynx, or in both.

2. It is absent in non-phthisical disease, in some cases of chronic (fibroid) phthisis, and during quiescent stages of the disease.

3. It is found in greatest numbers in acute phthisis with fever, softening, and cavity formation, but is also present in fair numbers before consolidation can be detected, especially if the larynx be affected, and it is thus useful in the diagnosis of incipient phthisis.

4. In a given case its numbers vary according to the nature and origin of the pulmonary secretion, and the period of the day at which it is expectorated, as also according to whether it is or is not free from extraneous matter in excess—*e.g.*, gastric secretion, saliva, or blood.

5. Found in the laryngeal secretion on its direct removal, it is a most valuable aid in the diagnosis of laryngeal tuberculosis.

6. In hemorrhage from the lungs, the presence or absence of tubercle bacilli in the hemorrhagic fluid has a most material influence on the prognosis.

7. Negative results in important or dubious cases cannot be held as conclusive unless examinations by different methods have been made on at least three different occasions.

8. Whilst its diagnostic value is thus of a very high standard, indicating the existence of tubercular disease, its prognostic value cannot be determined with accu-

[1] See THE MEDICAL NEWS, January 26, 1884, p. 89.

racy, inasmuch as it may be as abundant in a comparatively slow non-febrile case as it is in a more acute and febrile one.—*Edinb. Med. Journ.*, February, 1884.

Action of Aconitine on the Heart.—When one studies, says M. Laborde, the action of crystallized aconitine on the heart of the frog, the following results are constantly obtained: with very small doses, about gr. $\frac{1}{320}$, after four or five minutes, a progressive acceleration is noted, which tends to tetanic arrest. After this, the heart regains its normal function, as though the aconitine acted in the same manner as section of the pneumogastric. A proof experiment confirms the results recently announced by François-Franck; if the action of the pneumogastrics is suppressed, either by atropine or curare, the typical action of aconitine does not appear. It would seem that the drug does not affect the intracardiac ganglia, nor the central end of the pneumogastric.—*Gazette Hebdom.*, February 1, 1884.

A Vibrio Observed During Measles.—M. J. A. Le Bel reports that he has observed in the urine, during measles alone, the appearance of a slightly curved rod, very refracting, about one inch in diameter and endowed with very slow movements. The length varies considerably, so that the observer sees them of every appearance, from that of the typical vibrio to that of the bacteria.

In the case of ordinary measles, this vibrion only appears in the urine during a few days, and disappears almost simultaneously with the appearance of the fever and swelling of the face. He has observed, in the case of an infant, on the second day of the eruption, the vibrio and spores; the protoplasm which enveloped them disappeared very rapidly.

The naturally acid urine is a favorable soil for this micro-organism; it may be found in abundance in the vessels in which the urine is placed, distributed in the mass of the liquid. It is well, if one wishes to judge of the intensity of any particular attack, to examine each specimen of urine as it is passed.

This vibrio makes its second appearance at the desquamative stage; at that time also it is easy to recognize it. The skin may be scraped and the scales placed first in sterilized water and then in sterilized urine; within twenty-four hours large numbers of the micro-organism may be seen. In severe and persistent cases, it reappears in the urine and on the skin for weeks and even months.

Le Bel states that he has been extremely careful in his observations, and has no reason to think that they are not correct.—*Journ. de Méd. de Paris*, Jan. 19, 1884.

Traumaticine.—Traumaticine is the name given by Schivardi to the solution of one part of pure guttapercha in ten parts of chloroform, and may be used as the vehicle for the application of various substances to the skin. It forms on the skin a hard, resistant, and lasting pellicle. The solution can be made ready for application in a very few moments. The slow volatilization of the chloroform from the mixture enables one to use it for frictional applications.

Traumaticine is not irritating, and has also the advantage of being cheap. It has been especially recommended by Prof. Auspitz. In the treatment of psoriasis, he uses a ten per cent. solution of traumaticine and chrysarobin; after having detached the greater part of the scales by a soap-bath, the solution is applied, by means of a fine, short brush, to the patches, the part being rubbed with the brush. Each application is preceded by a soap-bath—repeated more or less frequently, according to the intensity of the affection. In a few cases, one application a day will suffice, and the patient is cured in four or five days. The application never causes the least irritation. Auspitz has several times used it for herpes tonsurans, eczema marginatum, and prurigo. In the last affection, a ten per cent. solution may be used for adults, and a five per cent. for children; ordinarily the prurigo disappears suddenly.

Traumaticine is also a good excipient for pyrogallic and salicylic acids. Schivardi uses it in the treatment of chilblains, and proposes it as a remedy in acute orchitis.—*Gazz. degli Ospitali*, December 29, 1883.

Obliteration of the Abdominal Aorta.—Gyselynek reports the case of an officer, æt. 23 years, addicted to drink, and under treatment for syphilis for a period of three years, who died of gangrene of the lower limbs. He had suffered for five years with palpitation of the heart, symptoms of oppression, slight cyanosis, and a quick, small pulse. On the fourth day after admission to the hospital, the lower extremities became cold, and he complained of pain along the larger vessels. This was followed by loss of sensibility in the legs and increased temperature. On the seventh day, gangrene set in, and gradually extended upward to the sacrum, when the patient died on the thirtieth day. The autopsy showed that the aorta was obliterated by a thrombosis just above the bifurcation. The centre of the thrombus contained micrococci.—*Centralbl. für Chirurgie*, December 22, 1883.

Cockleburr in the Larynx; Laryngotomy. Dr. E. Van Note reports the case of a girl, æt. 11 years, who accidentally got a cockleburr into the larynx. Having attempted in vain to remove the foreign body through the mouth, laryngotomy was performed two days after the accident, and the burr removed. The child made an easy and quick recovery.—*St. Louis Courier of Med.*, February, 1884.

Total Vaginal Extirpation of the Uterus.—Dr. W. A. Duncan successfully removed the entire uterus, per vaginam, for malignant disease, on January 22d, at the Royal Hospital for Women and Children. The patient, according to the *Lancet* of January 26th, is progressing satisfactorily.

Antifermentative Properties of Bichromate of Potash.—Dr. Laujorrois has recently made experiments which have demonstrated that bichromate of potash possesses antifermentative and disinfectant properties to a high degree. Bichromatization (the word by which he expresses his new method of disinfection) will indefinitely protect animal matters from the action of the causes of putrefaction.

In March, 1876, a physician sent to Dr. Laujorrois a scirrhus of the mammary gland, which he had removed. It was macerated for a month, at a temperature of 10° or 12° C., in an aqueous solution of bichromate of potash (grs. v. to f℥j.). It was then taken out and exposed to the free air, without any covering to protect it from the

action of external agents. Since that time it has undergone extreme variations of heat and moisture, but in November, 1882, it showed no sign of putrefaction.

In February, 1882, he placed five hundred grammes of urine in an open vessel and added five grammes of bichromate of potash to it. Eight months afterward, the urine thus bichromatized, presented no sign of putrefaction. It was clear, limpid, and without sediment or odor. Human blood, treated in the same manner, was found to be equally well protected against putrefaction.

The excrements of phthisical patients mixed with a 1 to 100 solution of bichromate of potash, immediately lost all odor. Milk has been treated in this manner, and with the same results as to the absence of putrefaction.

Laujorrois reports a case of malignant pustule treated by incision and bichromate dressing 1 to 100, and the patient was cured on the fifteenth day.—*Journ. de Méd. de Paris*, December 29, 1883.

MOIST GANGRENE OF FOOT AND LEG TREATED BY AMPUTATION THROUGH THE MIDDLE OF THIGH.—The following case, under the care of MR. PAGE at Newcastle-upon-Tyne Infirmary, is confirmatory of the views expressed in an editorial in THE MEDICAL NEWS, of January 5.

A gardener, aged fifty-nine years, a very intemperate man, was admitted on September 13, 1883, in consequence of moist gangrene of the right foot and leg. The disease commenced thirteen weeks previously, and it was still progressing. All the toes had separated. The whole of the foot was dead, and a large patch of gangrene had just appeared on the outer side of the leg. The stench was intolerable, and the man was reduced to such an extent by pain and exhaustion that it seemed probable, if unrelieved, he would not survive many days. His whole arterial system was in a very pronounced condition of calcareous degeneration. On September 14, the limb was amputated through the middle of thigh. The femoral artery was so much diseased that an attack of secondary hemorrhage was fully anticipated; but all went well, and on September 24, the antiseptic dressings were discontinued, as the wound was entirely healed. The patient remained in hospital till October 21, and was then discharged with a good sound stump.

Whether it is better to amputate or not in cases of spontaneous moist gangrene, and if so, where and at what stage of the disease, are questions upon which there is room for much difference of opinion. In every instance in which Mr. Page has waited for a line of demarcation to form, the patient has died exhausted. In this case the relief which followed the removal of the limb was immediate; the tongue became moist, the look of prostration soon passed away, the patient was at once able to sleep and to eat, and the wound healed by first intention.—*Lancet*, January 5, 1884.

AN IMPROVED METHOD OF AMPUTATING THE PENIS.—SURGEON-MAJOR T. J. MCGANN gives the outlines of four cases of amputation of the penis by the following method: The patient is placed on the table in the lithotomy position, and chloroform having been given, an assistant, holding the scrotum in both hands, draws it forwards, keeping the raphe of the scrotum and perineum in the same line. An incision of two and a half or three inches in length is made behind the scrotum in the median line, with its centre over the bulb; the corpus spongiosum having been completely exposed, and a little fine dissection made so as to separate it laterally from the corpus cavernosum, the scrotum is allowed to drop and is drawn slightly backwards, and the penis having been seized, is pulled forwards and removed by a single sweep of the knife close under the pubis. The few bleeding vessels having been twisted or tied, the scrotum is again drawn forwards as before, when the cut surface of the corpus spongiosum presents itself through the posterior incision, and this being separated from the corpus cavernosum, is turned down into the perineum, and left hanging out there half an inch beyond the level of the skin. The front and back incisions are then united by a few points of suture, and the protruding spongy body slit on the lower or posterior aspect and the edges united to the perineal skin on either side by two points of suture. The operation is completed.

On the completion of the operation there is but a small wound visible in front, and the scrotum, which is practically intact, has to be raised to render the posterior incision visible.—*Indian Med. Gazette*, December, 1883.

A NEW MERCURIAL PREPARATION; HYDRARGYRI TANNICUM OXYDULATUM.—DR. SIGMUND LUSTGARTEN has recently called attention to the chemical and therapeutic properties of a new mercurial salt, which he prepared in the laboratory of Prof. E. Ludwig, and which he has employed in the different forms of syphilis.

This salt is the tannate of the protoxide of mercury (hydrargyri tannicum oxydulatum), which contains fifty per cent. of mercury. It is a dull green powder, without odor or taste, and is only soluble when decomposed. Hydrochloric acid makes no sensible impression upon it, but very dilute alkalies, ammonia, solution of caustic potash, and the alkaline carbonates, reduce it in a short time to a sort of magma composed of very small particles of metallic mercury. They are so minute that the greater part of them present, under the microscope, the phenomenon known as molecular movement. This process of reduction is produced under the influence of the alkaline reaction of the intestinal juices; whence, it may be asked, if the absorption of the particles of mercury is produced in the same way in the intestines as on the skin by mercurial friction? The determination of this question has occupied the attention of Lustgarten for some time. He has now been able to demonstrate the rapidity of the absorption of mercury into the blood, having found mercury in the urine in twenty-four hours after its administration.

This new drug has been prescribed in two or three doses of grs. jss every day, but in spite of this seemingly large dose no troubles of the stomach and bowels have been observed, nor the troubles usually seen when the ordinary mercurial preparations—calomel or corrosive sublimate—are administered; nor has stomatitis or salivation been observed, although the very large dose of grs. xc has been given. On the contrary, in ten cases treated, up to this time, comprising every period of syphilis, and especially cases of relapse of a very rebellious nature, as syphilides with small papules and pustular syphilides, there was so rapid a regression of the lesions that Lustgarten does not hesitate to place the new drug by the side of the best mercurial preparations hitherto employed. —*Ann. de Dermat. et de Syphil.*, January 25, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, MARCH 8, 1884.

THE TREATMENT OF DIPHTHERIA.

IN an editorial last week we considered the subject of the topical treatment of diphtheria. We now turn our attention to its systemic management.

Medicines, properly speaking, are prescribed in diphtheria for two purposes: to check the exudation, and to prevent the diffusion of the germs of the poison. Certain special indications are afforded in the state of particular organs; as, for example, irritability of the stomach; endocarditis; albuminuria; delirium; each of which may demand special attention. Again, the method of treatment may be merely symptomatic, or it may be specific—directed against the symptoms as they appear; or used to produce a curative effect by some unknown influence over the *fons et origo mali*. As, in the present state of uncertainty regarding the latter, the remedies which have a truly specific character cannot be determined, it will be better to consider the treatment from the symptomatic point of view.

Rarely are antipyretic remedies necessary. In the more formidable cases, the temperature may be but little elevated, may, indeed, be subnormal. In the more vigorous subjects, having a sthenic activity, the first signs of faucial inflammation are best encountered with the tincture of aconite root, one or two drops every hour or two. If, on the other hand, circulatory depression and low or subnormal temperature are the conditions present, good results are had from belladonna tincture, two to five drops every three to six hours. As an irritable stomach may be present from the very beginning, the remedies used must be directed to this symptom. Then creasote, or carbolic acid, with or without tincture of iodine, becomes exceedingly useful. If convulsive phenomena, excessive nausea, and depression of the circulation coexist at this period, calomel in small doses—one-fourth, one-half, to one grain—given at short intervals has an excellent effect in checking the nausea and the nervous disturbance. When the cathartic action takes place, it should be discontinued, and carbolic acid or creasote given.

Bromide of ammonium appears to us to have an excellent effect in checking the diphtheritic exudation. It has a sedative action on the fauces, and, being eliminated, in part, by the mucous membrane of the pharynx, makes a local impression antagonistic to the morbid action. It may, therefore, be regarded as having an action of specificity—as an agent destructive of the microbes undergoing multiplication in the mucous membrane. The time for its administration is when the exudative process is beginning, and before systemic infection, or, at least, systemic depression, has occurred. It is not useful when the condition of gangrene, or septicæmia, or decided adynamia is present. It should be given in moderate doses of three to ten grains, frequently, and well diluted.

The most popular remedy in diphtheria, amongst the profession at large, is chlorate of potassium. There is a notion prevalent that it has a specific action. The origin of this conception is obvious. In certain cases of stomatitis the curative action of chlorate of potassium has that degree of certainty and promptness which belongs to the effect regarded as "specific." Its use in diphtheria has been generalized from this admitted curative action in stomatitis in accordance with the ancient therapeutical maxim—"a remedy which has proved curative in one case, must act beneficially in analogous cases." In this instance, as in so many others, the rule is fallacious. The good results due apparently to the chlorate, are, in many cases, only the outcome of the *post hoc*. All objections considered, there is still a mass of clinical observation more or less favorable to its use. We may admit that in the early stages of diphtheria it can do some good, but if the kidneys become damaged it not only ceases to be useful, but may be injurious. If, as Feltz and Ritter have shown, the symptoms of uræmia are due to the retention of the potassium salts in the blood, the exhibition of the chlorate can only increase the head symptoms.

The combination of the tincture of ferric chloride with chlorate of potassium is probably more widely used than the latter alone, and, doubtless, justly so. Clinical experience appears to be in favor of the combination, but how far its utility is supported

numerically remains to be shown. Good results have, apparently, been produced by the topical application of the solution, conjoined with its stomachal administration.

Since Guttmann's very enthusiastic introduction of pilocarpine, the utility of this remedy has been both denied and reaffirmed. It acts surprisingly well in some cases, but is entirely unsuited to the greatest number. When the false membrane is not extensive, tends toward or invades the larynx, and the vital forces are not depressed, pilocarpine softens and detaches the exudation, and has a favorable influence over the subsequent progress of the case. In the septicæmic form of diphtheria it is generally contraindicated, but in the event of urinary suppression it may render an important service. Whenever cardiac failure is threatened it is inadmissible. Notwithstanding the limitations imposed to its use by reason of its depressant action, cases have come to our knowledge in which, although the contraindications were pronounced, and the general aspect unfavorable, it proved remarkably effective.

The increasing importance of the germ theory, and the unquestionably good effects of that class of remedies known as germicide, render the use of certain antiseptic agents highly interesting and suggestive. Quinine belongs to this group. It is employed, however, rather to stimulate the vital processes than to arrest the development of microbes. Indeed, it may be well questioned whether it can destroy the micrococcus of diphtheria, as it surely cannot prevent its pullulation. The use of large doses is to be deprecated, for the depression of function thereby caused cannot fail to be injurious. On the other hand, small doses serve a useful purpose in promoting the activity of the assimilative functions.

Unquestionably, the most powerful antiseptic now available for the destruction of germs is the corrosive chloride of mercury. It has been shown, also, that this agent is, within certain limits, a reconstituent tonic. In addition to theoretical considerations, clinical experience can be adduced in its favor. There is a growing disposition to regard it as the most important means now available to check the formation of false membrane, and to prevent the diffusion of germs from the point of local infection. Calomel, in part converted into bichloride, probably, acts similarly. This remedy has long occupied a high place in the esteem of a few practitioners who have employed it in the so-called true croup, as a sedative and an aplastic agent. With this view, doses of calomel, which must be regarded as "massive"—from five grains to a scruple every four hours—have been employed with asserted advantage. Any curative effect exerted by mercurials must be referred to three chief influences: parasiticide, aplastic, and eliminant. Doubt no longer exists in regard to the parasiticide power of the corrosive chloride, and calomel, although less active, must possess somewhat of the same property. Although we believe that, in general, mercurials do not affect the formation of false membrane in diphtheria, they act in one respect like pilocarpine; they act on the glandular apparatus of the mouth and fauces; the exudation is softened and detached, and, probably, its reformation checked. To these effects of mercurials must be added the eliminant. The stools produced by the purgative action of calomel in cases of diphtheria are peculiar in appearance and character, and are offensive in a marked degree. Septic materials are thus eliminated from the system.

Iodine has a place similar to that occupied by mercury. It is destructive of germs, hinders their diffusion, and checks the fermentative process, to which they are necessary. Its utility is, in our judgment, very great. The best form of administration is Lugol's solution, and with this may be combined carbolic acid, especially when the stomach is irritable, and when more active antiseptic action is demanded.

The phenol group, composed of carbolic acid, salicylic acid, resorcin, thymol, chinolin, and some others, from the theoretical standpoint, should have a good effect by destroying the specific germs, and arresting the morbid fermentations, either initiated or promoted by them. The practical results achieved by these remedies are not equalled by the expectations which *a priori* would be formed of their utility. The best effects have been witnessed from resorcin. Probably, phenoresorcin will prove still more useful. Allied to the agents of this group are eucalyptol and turpentine, both of which have been used with, apparently, good results. Whilst the phenol remedies are prescribed with reference to their antiseptic powers, eucalyptol and turpentine are indicated when the surface is cyanosed and the circulation feeble.

The complications of diphtheria demanding interference are, properly speaking, mere incidents in the course of a disease which may leave no single organ unharmed. The extension of the exudation to the nasal or laryngeal mucous membrane; the paralytic phenomena; the cardiac changes, and the kidney lesions, are the most important. Besides the treatment appropriate to the disease in any situation, special measures are necessary for these complicating conditions. It is more especially in laryngeal diphtheria that pilocarpine, bromide of ammonium, calomel, and lime-water spray are suitable remedies. In nasal diphtheria, the local use of carbolic acid, carbolate of iodine, and resorcin solutions, following a preparatory treatment by the

solvents; and the systemic treatment by alcohol, corrosive sublimate, and quinine.

As the paralytic phenomena play a serious *rôle* in the morbid complexus, it is in a high degree important to prevent the functional derangement of the nerve centres, on which the loss of power depends. The precise seat of the disturbance of function has not been fixed on, but some recent observations tend to establish the existence of temporary lesions of the multipolar ganglion cells of the anterior cornua, and of the nerve trunks. The ganglia of the sympathetic are probably the media through which the impressions are conveyed to the nerve centres. It follows that the remedies best adapted to act on the paralysis are picrotoxin, ergot, belladonna, and digitalis. The usual error consists in waiting for some overt act before prescribing for the paralysis, and sudden death may signify choking of the glottis, paralytic congestion of the lungs, or a weakened heart. For the last mentioned and the sluggish circulation dependent thereon, we have a hopeful remedy in nitroglycerine. As endocarditis and interstitial nephritis may be due to migrating micrococci colonies, the most effective remedy will be corrosive sublimate.

A wise and diligent supervision should be maintained over every case of diphtheria until complete restoration to health will warrant security. The mildest case is not without its evil side. Any case may consist in a succession of surprises. He will prove the most successful therapeutist who conjoins to careful management of existing conditions judicious provision against possible accidents.

MICROCOCCI AND ACUTE SUPPURATION.

From observations published by Ogston, of Aberdeen, in 1880 and 1881, it would appear that micrococci are the exciting causes of acute suppuration. Thus, the contents of seventy-four ordinary abscesses, examined immediately after their evacuation, disclosed an abundance of these organisms, which had penetrated into the tissues without any injury of the surface. Inserted under the skin of small animals, the pus ordinarily set up suppurative inflammation, and the animals exhibited signs of febrile disturbance. In chronic or scrofulous abscesses, on the other hand, micrococci could not be detected, nor was the injection of the pus contained in them followed by abscess or illness.

The conclusions of Ogston have not been confirmed by more recent experiments conducted by German pathologists. In Virchow's *Archiv*, Bde. lxxxvi., xc., and xcii., may be found papers from the pens of Ustkoff, Orthmann, and Councilman, which represent not only their own views, but those of Ponfick, Rosenbach, and Cohnheim, as to the occurrence of suppuration without the intervention of low forms of life. Through the subcutaneous injection of oil of turpentine, croton oil, and olive oil, under antiseptic precautions, suppuration was provoked, but the pus did not contain micrococci.

The experiments of the German observers demonstrate the occurrence of acute suppuration without the presence and intervention of micrococci, and render the position of Ogston, to say the least, questionable. Still more recently, however, Straus, in a contribution to the *Bulletin de la Société de Biologie*, for 1883, has repeated these investigations, and reached the conclusion that not only are micrococci essential to the formation of pus, but that the irritants employed by his predecessors are not pyogenic, although they are phlogogenic. In other words, the German observers induced suppuration by irritating injections, but their methods were faulty in that they permitted the entrance of germs beneath the skin which they failed to detect. Straus found micrococci in the five cases out of eighteen in which pus followed the insertion of oil of turpentine; and he bases the correctness of his statements upon the thirteen negative results, without appearing to imagine that his methods may be considered faulty.

We may be permitted to say that pathologists demand more convincing proofs of the causal connection between micrococci and acute suppuration than have as yet been presented to them. One set of observers assert one thing, another set, equally dogmatic, assert another; and it would be strange indeed if their followers were able to reconcile their conflicting views. Will not Koch and his equally careful assistants undertake the solution of this vexed and interesting question?

TOXIC EFFECTS FROM EMETIC DOSES OF TURPETH MINERAL.

The cases reported in our issue of this week showing the toxic effects of subsulphate of mercury, when given as an emetic, are peculiarly timely—for, as the reporters state, the use of this remedy has been increasing. The popularity of this emetic is owing to the unqualified praise of Dr. Barker, to whom the modern revival of this remedy is due. In his article commending it, Dr. Barker makes no distinction as to the form of croup requiring it, nor does he differentiate between true croup and pseudo-croup. It is true, he makes several varieties, which it must be admitted have no pathological existence, but much the largest number of cases in which his croup powders are used, are really examples of laryngismus stridulus. It need hardly be asserted that in a malady so little important, so powerful a remedy is unadvisable.

The immunity with which turpeth mineral is given as an emetic, depends on the promptness and completeness of its action—on the return of the poison with the vomited matters. From this point of view a full dose is safer than a small one. But not all subjects are equally susceptible to its action. There are some on whom it acts imperfectly and slowly, thus giving time for its irritant action. There are a few on whom it appears to have no proper emetic effect, and hence they suffer from gastro-enteric inflammation, and acute mercurialismus. We have known some instances of this kind, and can, therefore, confirm the observations of Drs. Randolph and Roussel.

All deductions made, there yet remain two classes of cases in which subsulphate of mercury is undeniably useful. First, the cases of "inflammatory croup"—so called by Dr. Barker—really examples of acute laryngitis; second, cases of true croup. In the light afforded by the accidents from its use, this remedy should not be administered in laryngismus stridulus.

THE ASSAY OF QUININE PILLS.

THE method for the assay of quinine pills, as detailed in a circular recently issued by Messrs. McKesson and Robbins, in accordance with their promise of last month to furnish a new and simple process, is, in a slightly modified form, that most commonly adopted by chemists for such investigations, with the application of the same principle adopted by THE MEDICAL NEWS COMMISSION in its investigation of the commercial samples of the article.

This method consists essentially in dissolving a definite number of the pills in water acidulated with diluted sulphuric acid, by the aid of a gentle heat, precipitating the alkaloid by ammonia water, and subsequently abstracting the alkaloid from the mixture by means of ether. While, however, in our previously reported analyses, the mixtures containing the alkaloid, made alkaline by ammonia water, were agitated with successive portions of pure ether until the aqueous liquid, after acidulation, no longer afforded any reaction with alkaloidal reagents, and the entire amount of ethereal liquid afterward was evaporated, the proposed method of manipulation limits the amount of ether for the abstraction of the quinine from twenty grains of sulphate, to fifty cubic centimetres. By the subsequent evaporation of twenty-five cubic centimetres of the ethereal solution so obtained it is assumed that one-half of the alkaloid contained in the mixture will be thus represented.

Although the latter method of procedure, when carefully followed, will afford *approximately* correct results, which, indeed, is all that is claimed, it is questionable whether it would commend itself to careful analysts, or even in inexperienced hands afford results so satisfactory as the obtainment of *all* the alkaloid by the use of larger and successive portions of ether.

For the evaporation of the ethereal solution, the use of a watch-glass, as recommended in the process, is open to serious objection. The extreme volatility of ether, together with the remarkable density of its vapor, would, with the greatest care, almost necessarily involve considerable loss in its evaporation from so shallow a surface, by spreading over the edge of the receptacle; and a capacious tared glass capsule of greater depth, or a tared glass flask, would be much better adapted to the purpose.

Since crystallized quinine loses its water of crystallization at 125° C., and fuses at 168° C., the directions to heat the evaporated product "strongly" by holding the glass, with "a pair of crucible tongs or any convenient substitute, over a gas or spirit flame," should be followed with considerable caution to avoid decomposition; when available, a hot air-bath, with proper regulation of temperature, would be far preferable to the application of direct heat for the dehydration of the alkaloid.

In the calculation of the result of an analysis, instead of multiplying the amount of anhydrous alkaloid obtained by 436, and dividing the product by 324, it need but be multiplied by the factor 1.3456, when the product will at once represent the corresponding amount of crystallized sulphate $(C_{20}H_{24}N_2O_2)_2H_2SO_4,7H_2O$.

In the test for the purity of the quinine, the amount of ether directed to be employed to dissolve the latter ("six times its weight of ether, sp. gr. 0.725") appears remarkably small, since the United States Pharmacopœia and other authorities state that crystallized quinine requires about *twenty-five parts of ether* for solution.

THE CHOLERA BACILLUS.

IN another column will be found a statement of the latest results of the labors of the German Cholera Commission now in Calcutta, which, with the letter of our Berlin correspondent, furnishes the full text of Koch's fifth report.

It will be noted that there were found in the intestines of cholera patients the same bacilli as were found in Egypt; that these bacilli were isolated and successfully cultured, and that they possessed characteristic properties as to form and growth, and can now be recognized with certainty from other bacilli. These characteristics are not described in detail, but no bacilli presenting them have been found in the intestines of eight persons dying of other diseases, or in the intestinal contents of

other animals or in other substances rich in bacteria. It need scarcely be said that these results are of the greatest importance.

The profession will await with interest the reception which will be given by the savants of the French capital to Koch's explanation of the discrepant results obtained by the French Commission in Egypt. For it is scarcely conceivable that the members of the Commission selected by the distinguished Pasteur should know so little of the histology of the blood as to be misled by blood-plates.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Convention for Organization held in Albany, February 4th and 6th, 1884.

MONDAY, FEBRUARY 4TH. FIRST SESSION.

In compliance with an invitation issued during the last week of January, a number of members of the medical profession of the State of New York assembled in the parlors of the Delavan House, Albany, at 8.30 P.M., February 4, 1884.

After calling the roll, seventy-six being present (more entered the rooms later, making a total of about one hundred), the object of the convention was briefly stated by DR. J. W. S. GOULEY, of New York, as follows:

In view of the dissension which has been created in the Medical Society of the State of New York by the radical change made in its Code of Ethics, it was suggested that a convention be held on the day preceding the session of the State Society, to discuss the question of this change in all its aspects, and finally to take such action as the majority assembled should decide upon. Therefore it is, Gentlemen, that you have been invited to meet here by members of the profession who have signed the call for the convention, which is as follows:

The undersigned, permanent members of, and delegates to, the Medical Society of the State of New York, request you to attend a meeting to be held in the parlors of the Delavan House, Albany, on Monday evening, February 4th, at 8.30 o'clock, to take into consideration the question of the Code of Ethics, which will come up before that Society on the day following.

TEMPORARY OFFICERS.

DR. H. D. DIDAMA, of Onondaga County, was called to the Chair, and DR. CHARLES S. WARD, of New York County, was appointed Secretary.

On taking the Chair, DR. DIDAMA stated that the object of the conference was to exchange opinions regarding the proper course to be pursued by the adherents of the National Code of Ethics.

Telegrams were read from Drs. John P. Gray, of Utica; J. G. Orton, of Binghamton, and C. C. F. Gay, of Buffalo, regretting their inability to be present.

THE CANVASS OF THE STATE.

DR. GOULEY, of New York, then presented a report of the canvass of the State, and made the following statement:

Total number of physicians in the State,	5002
Number of those who have not expressed their preference,	1142
Total number of votes recorded,	3860

The recorded votes are as follows:

For the National Code,	2547
For the "New Code,"	1040
For no code,	239
Unclassified,	34
Total,	3860

It is evident from these figures, he said, that there is a majority for the National Code over the whole number of committed and uncommitted. That there is a majority of more than two-thirds for the National Code over the "New Code," and a nearly two-thirds majority for the National Code over the "New Code," no code, and unclassified combined.

It is now proper that you should know how stands the vote in the State Society; and here let me say that, although we have a majority, our adherents will do as they have done before—stay away—and we shall be outvoted. I doubt much if on Tuesday night we poll more than one hundred votes. According to the *Transactions* of 1883, the State Society has thirty-three retired members, who are not entitled to vote, and should have 386 voting members and delegates, but I cannot count more than 382.

Of these there are for the National Code,	193
For the "New Code,"	134
For no code,	19
Uncommitted,	36
	382

Now, Gentlemen, that you have before you these facts and figures, I leave you to decide what measures it may be wise for this assembly of representative men to take.

TO VOTE AGAINST THE NEW CODE.

DR. E. D. FERGUSON, of Rensselaer Co., moved that all the members and delegates present in Albany, who are in favor of the reënactment of the National Code, be requested to attend the meeting of the State Society on Tuesday evening, for the purpose of protesting, by their vote, against the action taken by the Society in substituting the "New" for the National Code, and of endeavoring to secure the reënactment of the National Code.

DR. T. F. ROCHESTER, of Erie Co., seconded the resolution, and said that the members and delegates would fail in their duty if they did not present this protest.

DR. AUSTIN FLINT, JR., of New York, said: It is more than a year since I have publicly spoken to an audience of friends on the questions which have at last divided the medical profession of the State of New York. As you all well know, thus far the battle-field in the warfare against the honor and dignity of the profession has been mainly in the City of New York. In the City of New York, the conspiracy, which has brought about the deplorable conflict that has been forced upon us, had its inception. The attack upon the most sacred traditions of our profession was there made with a malignant rancor that can only be fully appreciated by

those who have been personally involved in this unhappy contest. Our experience teaches us that but one course is now open to those who are unwilling to remain in the false and humiliating position in which we are placed. The proper course is for us to organize a new State Association, to be composed exclusively of those who refuse to countenance professional relations with irregular practitioners.

The loyal members of the profession in the County of New York, having exhausted all proper means of resistance in the existing Societies, and with an untarnished record as regards the methods employed by them in the contest, have organized on a permanent basis, the New York County Medical Association, composed exclusively of those who uphold the National Code of Ethics.

To-night we should organize a New York State Medical Association. The issue has been forced upon us. We stand in the presence of the actual fact of a divided profession. The State Society and the Society of the County of New York have seceded from the regular profession of the United States. We made no movement looking to the formation of a loyal State Association until the most vigorous efforts to redeem the existing Societies had signally and hopelessly failed. We are now cast out of fellowship with the regular profession of this great country, as represented in the American Medical Association and in the medical societies of other States. We must redeem the State of New York. There remains but one course to pursue, and that is to form an Association of our own.

I hope, Mr. Chairman, that a New York State Medical Association will be organized to-night, in affiliation with the regular profession of the United States; that the existing County Societies whose membership is loyal will put themselves at once in affiliation with the new State Association; and that, in counties in which the existing societies cannot be brought in bodily, new Associations will be promptly organized, to be composed exclusively of members of the profession who uphold the National Code of Ethics.

While holding to these views, I am cordially in favor of the resolution offered by Dr. Ferguson, simply in order that we may put ourselves on record in the State Society, as I believe, for the last time.

DR. C. G. BACON, of Oswego Co., was in favor of Dr. Ferguson's resolution, and of continued efforts from year to year, until success should be achieved.

DR. FERGUSON, with the consent of Dr. Rochester, temporarily withdrew his resolution.

THE ORGANIZATION OF A NEW STATE ASSOCIATION.

DR. AUSTIN FLINT, SR., of New York, after stating that he thought it improbable that a two-thirds vote could be obtained in the State Society in favor of reënacting the National Code of Ethics, and that consequently the time had arrived for the formation of a new State Association, introduced, with a preamble reciting the well-known circumstances under which the "New Code" was adopted, the following resolution:

Resolved, That the members of the medical profession of the State of New York, here convened, do now unite in forming an organization to be known as the NEW YORK STATE MEDICAL ASSOCIATION.

The resolution was seconded by DR. FREDERICK HYDE, of Cortland Co., in a fitting speech.

DR. E. M. MOORE, of Rochester, could not believe that the time had arrived for the formation of an association separated from the State Society. He thought there had not yet been opportunity to have full expression in the State Society of opinion from the whole State, and he was in favor of postponing the organization of the association until Wednesday morning, at which time we should be better informed, and therefore better prepared with reference to our future action.

DR. ROCHESTER, of Buffalo, was very glad to think that there was a prospect of a medical association which would be strictly voluntary without any hampering by State legislation.

DR. ELY VAN DE WARKER, of Syracuse, said:

Certain issues growing out of this contest in the State Society must be grappled fearlessly, for they are inevitable. Peace can never be restored. We know this to-night just as well as we shall know it Wednesday morning. We shall go into the contest in the State Society on Tuesday night simply for form's sake, and without a hope that we shall reverse the policy of the Society; therefore I can see no reason to delay the preliminary formation of the new State Association.

Another thing which appears to me just as certain to grow out of this division is this: unless the unscrupulous minority which controls the State Society is made up of brag and bluster, they must go on with the work. Their aggressive policy must extend to the County Societies. It is one thing, by the preponderating influence of three great county organizations, to be able to control the State Society; it will be another thing to invade each county medical society, and coerce them all into conformity to the new order of things. To make the "New Code" the medical law of the land they must do this. To allow each county medical society to exist quietly with the Code of the American Medical Association as a part of its organic law is to admit cowardice, defeat, and a cringing fear of the storm they have raised. To do less than this will make them the laughing-stock of the world, and an object of contempt of all right-thinking men. They cannot go back, the day of strife is yet before them, as they will find out, and they must meet it. For this, let us prepare, let us fore-arm, let us prepare here in this great central association, and make a home for those county medical societies that will resist coercion! Here they can come and find comfort and protection. We owe them this protection, and we shall do less than our duty if we neglect the opportunity.

Drs. C. G. Pomeroy, of Wayne Co., Austin Flint, Jr., and Gouley, of New York, Seymour, of Rensselaer Co., and G. W. Cooke, of Ulster Co., urged the adoption of the resolution.

DR. E. D. FERGUSON, of Troy, spoke for the preamble and resolution, and moved that they be adopted to-night, but that such adoption should be in force only in case the State Society shall fail on Tuesday evening to reënact the National Code, otherwise the action of to-night shall be void.

DR. M. W. TOWNSEND, of Genesee Co., moved that Dr. Flint's preamble and resolution be laid on the table until Wednesday. Lost by a tie vote.

DR. GILLIS, of Franklin Co., and DR. J. C. GREENE, of

Erie Co., thought action on the resolution should be deferred until after the vote had been taken in the State Society on the resolution to restore the National Code.

DR. D. GUERNSEY, of Dutchess Co., DR. GOULEY, of New York, and DR. DIDAMA, of Syracuse, advocated the resolution. No harm, Dr. Didama thought, could come from our organization to-night. We can go to the State Society, enter our protest against the unfair and clandestine action of 1882, and ask that the National Code be restored. If, by some unexpected impulse of good judgment and kindly feeling, our appeal shall be heeded, then this Association may be discontinued. But if the minority should persist in trampling upon our rights—as we all believe they may—then, if we are men respecting ourselves and deserving the respect of our constituents, we shall reassemble on Wednesday morning, and end the fruitless and disgraceful wrangle of the past two years by finishing the good work we have so well begun this evening.

The motion to lay on the table was renewed, and lost by a rising vote of twenty-one for tabling and thirty-four against.

DR. FLINT'S preamble and resolution, with the limitation as to the time of enforcement as provided in the resolution offered by Dr. Ferguson, were then adopted; the vote, on motion of Dr. Rochester, being declared unanimous.

THE OBJECTS OF THE NEW ASSOCIATION.

DR. T. B. REYNOLDS, of Saratoga Co., offered the following:

Resolved: That the objects of this Association shall be the cultivation and advancement of the science of medicine. Carried unanimously.

DR. GOULEY offered the following

PLAN OF ORGANIZATION.

Resolved: That the following plan of organization be adopted:

1st. To facilitate the transaction of business, such as the selection of committees, the annual election of officers and of new members, etc., the State shall be divided into five geographical districts, to be called respectively, the 1st, or Northern District; the 2d, or Eastern District; the 3d, or Central District; the 4th, or Western District; and the 5th, or Southern District.

These districts shall comprise the sixty counties of the State.

2d. A Nominating Committee shall be created, to consist of two members from each of the above-named districts—elected by the representatives of each district—and one appointed at large by the Chair. In all eleven members.

3d. The Nominating Committee shall name, subject to the approval of the Association, a President and four Vice-Presidents—these five officers to come one from each of the five districts—a Recording Secretary, a Corresponding Secretary, and a Treasurer.

In addition, said Committee shall name two members from each district, who, together with the titular officers and one member appointed at large by the President-elect, shall constitute the Council, which shall manage the affairs of the Association.

The Nominating Committee shall suggest the time and place for holding the next session of the Association.

4th. The Council shall complete the organization, prepare a constitution and by-laws, in accord with this plan, to be presented at the next meeting of the Association, and file articles incorporating the New York State Medical Association, and also County Associations, as branches of said New York State Medical Association. The Council shall also assist the President in securing scientific contributions.

5th. In case no meeting of this Association be held prior to May, 1884, the Council shall appoint delegates to the National Association and to State Societies.

6th. The Council shall fill such vacancies as may occur in its body during the current year, except in the office of President and Vice-President.

7th. The ten members of the Council shall constitute a quorum.

8th. The initiation fee shall be five dollars, and the annual dues three dollars.

9th. The code of ethics, which shall form an integral part of the by-laws of this Association, shall be as follows:

The same as that adopted by the American Medical Association.

10th. The Association shall hold annually one session, which shall last three days or more.

The above plan of organization was adopted unanimously.

THE MEMBERSHIP.

DR. FERGUSON moved that all physicians in the State of New York who are in good standing in the present County Societies, and who subscribe to the code of ethics of this Association, can become members thereof upon paying the initiation fee and signing the constitution and by-laws. Carried unanimously.

DR. ROCHESTER moved that all questions relating to the admission of new members, prior to the permanen organization, shall be decided by the Council. Carried unanimously.

NEW COUNTY ASSOCIATIONS.

DR. HYDE moved that, after the formation of new County Associations as branches of this Association, the members of said County Associations may become members of the State Association by paying the initiation fee and signing the constitution and by-laws. Carried unanimously.

TO VOTE TO REPEAL THE NEW CODE IN THE STATE SOCIETY.

DR. FERGUSON then reintroduced his resolution concerning the attendance at the session of the State Society on Tuesday evening for protest against the present code, and for the support of the National Code. Carried unanimously.

The convention adjourned at 11.30 P.M., to meet at 9 A.M., Wednesday, February 6th.

[As is well known, the motion in the State Society to repeal the New Code was lost on the following evening.]

WEDNESDAY, FEBRUARY 6TH. SECOND SESSION.

The Association met in adjourned session at 9 A.M. The minutes of the first meeting were read and approved.

THE NOMINATING COMMITTEE.

The members from the five districts then met in separate portions of the room, and, after consultation,

presented the following list of names as the Nominating Committee, Dr. Austin Flint, Sr., being appointed a member at large by the Chair.

1st District.—Dr. Ira H. Abell, Antwerp, Jefferson Co.; Dr. L. C. Dodge, Rouse's Point, Clinton Co.

2d District.—Dr. T. B. Reynolds, Saratoga Springs, Saratoga Co.; Dr. Thomas Wilson, Claverack, Columbia Co.

3d District.—Dr. A. D. Head, Syracuse, Onondaga Co.; Dr. Caleb Green, Homer, Cortland Co.

4th District.—Dr. Darwin Colvin, Clyde, Wayne Co.; Dr. Thos. F. Rochester, Buffalo, Erie Co.

5th District.—Dr. D. Guernsey, Amenia, Dutchess Co.; Dr. J. W. S. Gouley, New York City and Co.

The Nominating Committee then retired.

DR. H. O. JEWETT asked for information concerning

THE RELATION OF THE ASSOCIATION TO COUNTY SOCIETIES.

The subject was informally discussed, and no action at present was favored, though the formation of County organizations in affiliation with this Association was considered desirable, and that, at a proper time, such measures should be taken as might be necessary.

THE NEXT PLACE OF MEETING.

DR. FLINT, JR., tendered the hospitalities of New York City for the next meeting of the Association.

DR. C. S. WOOD, of New York Co., offered a resolution that the invitation of Dr. Flint be accepted. Carried.

An informal expression of opinion was then requested as to the proper time for the next meeting of the Association, and finally a poll was taken of those who had preference as to the time of such meeting, which resulted in a majority favoring the third Tuesday in November.

DR. FLINT, JR., then moved that the third Tuesday in November of this year be appointed as the time for the next meeting of the Association.

ELECTION OF OFFICERS.

The Report of the Nominating Committee was then presented.

President.—Dr. H. D. Didama, Onondaga Co., 3d District.

Vice-Presidents, 1st District.—Dr. J. M. Crawe, Jefferson Co.

2d District.—Dr. Tabor B. Reynolds, Saratoga Co.

4th District.—Dr. B. L. Hovey, Monroe Co.

5th District.—Dr. N. C. Husted, Westchester Co.

Recording Secretary.—Dr. Caleb Green, Cortland Co.

Corresponding Secretary.—Dr. E. D. Ferguson, Rensalaer Co.

Treasurer.—Dr. John H. Hinton, New York Co.

Councillors, 1st District.—Dr. John P. Gray, Oneida Co.; Dr. Conant Sawyer, Essex Co.

2d District.—Dr. J. W. Moore, Albany Co.; Dr. Thomas Wilson, Columbia Co.

3d District.—Dr. Frederick Hyde, Cortland Co.; Dr. Ely Van de Warker, Onondaga Co.

4th District.—Dr. E. M. Moore, Monroe Co.; Dr. M. W. Townsend, Genesee Co.

5th District.—Dr. E. R. Squibb, Kings Co.; Dr. A. Flint, Jr., New York Co.

DR. E. M. MOORE moved that the report of the Nominating Committee be accepted, and it was then adopted unanimously.

MEMBER OF THE COUNCIL AT LARGE.

DR. DIDAMA, after thanking the Association for the honor conferred, appointed Dr. J. W. S. Gouley as member of the Council at large.

NEW MEMBERS.

DR. FERGUSON moved that the Council be authorized to receive new members. Carried.

DR. VAN DE WARKER moved that a Committee of three be appointed to secure the coöperation of a medical journal in sympathy with the wishes and interests of this Association. Carried, and referred to the Council for the appointment of such committee.

DR. H. B. ALLEN moved that the Corresponding Secretary be directed to furnish blank applications for fellowship. Carried.

A meeting of the Council was directed to be called immediately after the adjournment of the Association.

One hundred and sixty-eight members signed the agreement of organization.

The Association then adjourned to meet in New York City on the third Tuesday in November, 1884.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 18, 1884.

THE PRESIDENT, WILLIAM DETMOLD, M.D., IN THE CHAIR.

DR. GEORGE L. PEABODY presented a specimen of

SARCOMA OF THE DURA MATER.

The patient from whom the specimen was taken, he said, had been a man seventy-two years of age, who had died on the 9th of January last in the New York Hospital. As the autopsy revealed a large tumor, which made a considerable depression on the external convolutions of the brain, it had been a matter of interest to find out the clinical history of the case. The man had always been a free liver, though he was not intemperate in his habits.

About 7 P.M. on the 8th of January he slipped and fell violently on the pavement; but immediately got up without assistance and walked to a neighboring barroom, where he sat down. In fifteen minutes, however, he became unconscious, and was brought to the hospital. It was noted on his admission that there was a hæmatoma of some size under the scalp, on the left side of the cranium, and that there was some œdema of the lower extremities. The pulse was that of compression, slow and full (sixty-eight to the minute), and the temperature normal. Before death, however, both the pulse and temperature were considerably raised. The autopsy was made five hours after death. Extensive meningeal hemorrhage was found, which resulted from the rupture of a meningeal vessel at the time of the patient's fall, and was probably the cause of the coma. In the left parietal region was the tumor, which was flat on the side towards the dura mater, but convex on the surface that pressed upon the cerebral hemisphere. The case, Dr. Peabody said, was interesting as offering a contribution to the subject of cerebral localization, although a negative one. There was a large tumor pressing upon the brain to such an extent that it had made a well-marked depression of its surface; but the seat of the growth was

not in the motor tract. The patient had never had any paralysis, epileptic or apoplectic seizures, or even any headache, and his friends had never seen any reason to suppose that he had anything the matter with his brain. The autopsy also showed a condition of diffuse nephritis.

Dr. Gouley said that, twenty years ago, he had made the autopsy in the case of a young lady who had a much larger tumor of the dura mater than this, which pressed upon both hemispheres. It was of about the size of his fist. He had known the patient for some time, and she had never had any convulsions or any other symptoms referable to trouble in the brain; but the shape of her head was very peculiar, long and pointed like a sugar-loaf. When he had had the case under observation for about a year, the young lady died of perforation of the appendix vermiformis, and the autopsy revealed the presence of the tumor described. He had reported the case in the first number of the *New York Medical Journal*, in 1864, when it was published with a plate.

A SPECIMEN OF STENOSIS OF THE PULMONARY ARTERY.

Dr. Austin Flint, Sr., then presented a specimen, which he said was of rare interest, and which was at his disposal only for this evening. It was a heart presenting well-marked stenosis of the entrance to the pulmonary artery, in consequence of which the normal condition of the ventricles was exactly reversed, the left ventricle being much atrophied, and the right greatly hypertrophied. He believed the stenosis to have been congenital. The subject was a lad, nineteen years of age, who was admitted to the hospital for some trouble about his toe-nail. As he was seen on one occasion to have severe palpitation of the heart, an examination of the organ was made, when it was found that there was a loud systolic murmur present. It was supposed to be a mitral regurgitant murmur, although the situation of its maximum intensity was a little higher than ordinary. In reality the sound was produced by the sigmoid valves. The cause of death was scarlet fever. The patient had never had any cyanosis or other symptom indicating heart-trouble.

Dr. Janeway mentioned a case of stenosis of the pulmonary artery which he had seen several years ago. In this instance there was very marked cyanosis, and the patient finally died of phthisis. It was a remarkable case as showing the greatest amount of destruction and consolidation of lung tissue which he had ever seen compatible with the preservation of life, the autopsy revealing that only a portion of the lower lobe of one lung was in a serviceable condition. The cyanosis in this case seemed to be advantageous rather than otherwise.

Dr. Detmold then made some remarks on

THE DIAGNOSIS AND TREATMENT OF SYPHILIS.

All were aware of the difficulty sometimes met with in deciding whether certain symptoms seen in a patient were of a specific character or not, especially in cases in which the patient was unwilling to tell his true history or was really ignorant of his ever having had syphilis. There was one sign which he considered pathognomonic, although the text-books did not seem to attach much importance to it, and it had never yet deceived him. It was well known that certain diseases had special predilections for special tissues and organs. Thus, scrofula was particularly liable to attack bones with a large amount of cancellated structure, like the scapula and head and neck of the femur. Syphilis, on the other hand, selected an entirely different class of bones for its seat. It was the body of the bones which it attacked, and especially of those bones not covered by large masses of fibrous or muscular tissues. Of all other parts, it preferred the anterior aspect of the tibia; but was also very liable to attack the surface of the ulna, the sternum, the bones of the skull, and the bones of the nose. Whenever secondary syphilis gave rise to periostitis, it would be found that œdema over the part invariably resulted, and, moreover, that this œdema was permanent.

The pathognomonic sign of which he had spoken, was this permanent œdema over the anterior surface of the tibia. In no case, in all his experience, had he ever seen it entirely disappear, and hence its great diagnostic value.

He did not, of course, mean to say that œdema of this region was always of specific origin, as it was liable to result from injuries of various sorts; but when it was found on both tibiæ, and when no local cause could be discovered for it, there could be no reasonable doubt that it was due to syphilis. When periostitis had resulted in the formation of nodes, if seen in time, he was sometimes in the habit of denuding the periosteum subcutaneously, when the growth would disappear. A number of surgeons had confirmed by their observations his opinion in regard to the diagnostic value of permanent œdema on the tibia.

His treatment of syphilis was somewhat different, he continued, from that ordinarily employed. Some years ago a gentleman suffering from the disease had been under his care, who presented such an intolerance to mercury, as usually prescribed, that the treatment always had to be interrupted, and it seemed extremely difficult to secure a permanent cure. While in the army in Germany, Dr. Detmold had been familiar with the treatment by mercurial inunction carried to the point of salivation, which was then in vogue there; but this plan was obviously inapplicable in this case. He, therefore, made trial of the external use of a solution of bichloride of mercury, two grains to the ounce, which he instructed the patient to rub upon each of his extremities successively, using half an ounce of the solution at each application, night and morning.

The result was far beyond his anticipations, and since then he had constantly resorted to this plan of treatment, to the exclusion of all others. The application was perfectly clean, without inconvenience, without local effect upon the skin, never produced salivation, and, above all, was perfectly successful. He had thought in a few instances that he had observed griping pains in the stomach result from it after a time, and he had also occasionally noticed a slight discoloration of the finger-nails, which he was disposed to attribute to the friction in rubbing. He had, however, never observed the toe-nails to see whether they were discolored also. This treatment he preferred to any other with which he was acquainted, and it had now been tried successfully in various hospitals. Only a few days ago Dr. Leale had assured him of the great success which he had met with in carrying it out, and he trusted that any of those present who had not given it a trial, would do this whenever occasion should offer.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 25th, 1884.

THE PRESIDENT, S. OAKLEY VAN DER POEL, M.D., IN THE CHAIR.

DR. WM. S. HALSTED read a paper on

THE EFFECTS OF ADDUCTION AND ABDUCTION ON THE LENGTH OF THE LIMB, IN FRACTURES OF THE NECK OF THE FEMUR,

in which he claimed that, together with the measured length of the limb in such fractures, its position, as regards adduction or abduction, should be carefully noted; and that all statistics of these fractures were worthless which did not take into consideration the amount of adduction or abduction present. He had made a careful research in regard to the matter, and illustrated the points taken in the paper by a series of geometrical diagrams on the black-board.

DR. A. B. JUDSON said that while the paper was a scholarly attempt to apply an exact science to a problem in surgery, he was not sure that the point claimed was one of great practical importance. It seemed to him that the acetabulum was such a short distance from the head of the femur and the vertical line passing through the malleolus, that he doubted whether any great amount of measured shortening could be obtained by adduction or abduction.

DR. JOHN A. WYETH thought that the methods of measurement were all practically very inexact, and this was due in a great measure to the normal differences in the length of the femur, and of the entire limb on the two sides. This normal difference might even be as great as an inch, and it was a very rare thing to find the two limbs of exactly the same length. This consideration, in his opinion, did away with the possibility of making any satisfactory attempt to obtain accurate measurements. The difference was not great one way or the other in intracapsular fractures of the femur, and he thought it was not practicable to apply exactness of measurement to such accidental lesions.

DR. HALSTED said, in regard to Dr. Judson's idea, that the angle was too obtuse to be of any practical importance, and that he believed he was mistaken. In the case in Bellevue Hospital, which led him to make a special study of this subject, the patient stated that he had never had the slightest limp before. The apparent shortening was two inches, while the measured length of the injured limb was one-eighth of an inch greater than that of the other, and hence it was thought that there could be no fracture. He decided, however, that there was an intracapsular fracture. There were three things that he took into consideration: First, the adduction, making the limb longer; second, the adduction of the other limb, which was paralyzed, making it shorter; and, third, the fact that one limb might be naturally longer than the other. His demonstration had a direct bearing, he thought, on both diagnosis and treatment. With an adducted, impacted fracture, with apparent shortening, the patient was sure to limp.

NEW INVENTIONS.

NEW TRIAL-FRAMES.

BY L. WEBSTER FOX, M.D.,

OPHTHALMIC AND AURAL SURGEON TO THE GERMANTOWN HOSPITAL; CLINICAL ASSISTANT, EYE DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL, ETC.

THIS trial-frame for the adjustment of glasses, Fig. 1, consists of a horizontal bar upon which moves the frames for holding the trial lenses; these frames are moved by a screw (after the lunette du Dr. Armaignac) which adjusts the pupillary distance and registers the same.

The nose-rest is held in position by a screw, and can be elevated or lowered at will. That part of the frame for holding the lenses is divided into three spaces of sufficient width to allow the cylinder lenses to be rotated.

FIG. 1.

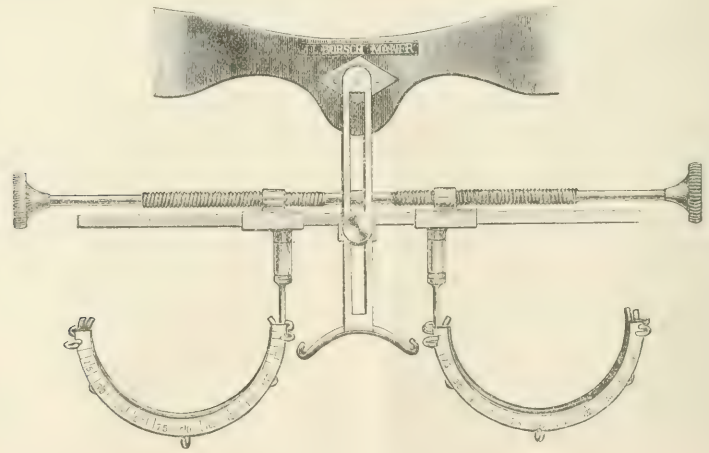

Fig. 2.

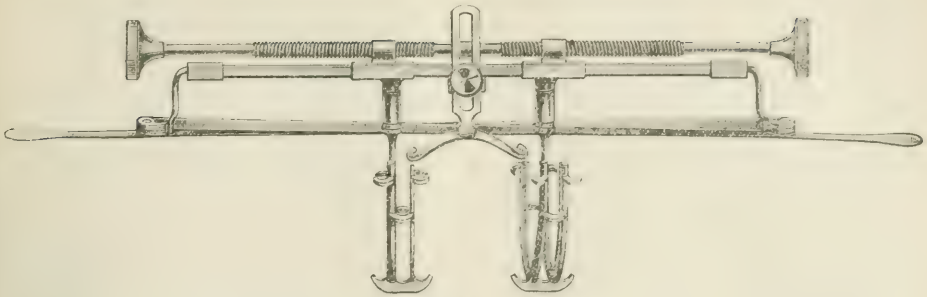

On the plate are engraved numbers indicating the axis of the cylinder

The frames holding the lenses are held in position by a socket-joint, which allows of their being turned forward on their axes. This obviates the necessity of either removing the trial lenses or elevating the frames, thereby exposing both eyes, when it is desirable to make a comparison test. The frames are held in position by a head-band or temples. The temples are fastened to the horizontal bar (see Fig. 2). Fastened to the temples are triangular-shaped wings, which prevent reflected light from falling on the posterior part of the lenses.

The woodcut drawings represent the exact size of the trial-frames. They are made out of a material combining lightness with strength and durability.

Fig. 2 represents the trial-frames with temples attached and the frames for holding the lenses turned forward.

John L. Borsch, Optician, 221 South Ninth Street, is the maker.

1506 Walnut Street

CORRESPONDENCE.

GEOGRAPHICAL DISTRIBUTION OF URINARY CALCULUS.

To the Editor of The Medical News.

Sir: Please allow me to correct a statement made by Dr. Keyes, of New York, in an article on "The Geographical Distribution of Urinary Calculus," etc., which appears in The News of March 1st. He states that "Mr. Dudgeon, of Pekin, who succeeded Kerr in China," etc. Dr. D. did not succeed Dr. Kerr, as I was Kerr's successor myself in the Native Hospital at Canton, and whilst there operated on some two hundred or more cases of lithotomy. In an article giving statistics of my first one hundred and forty cases, published in the "Medical Reports of the Chinese Customs," I give several reasons for the frequency of this disease in the Southern Province of China, all of which combine to produce it—amongst them the hard water used by the natives. Just at Canton, the water is soft; but had Dr. Dudgeon penetrated as far into the interior of the country as Dr. Kerr and I have done, I think he would have found the water which rushes down between those lime hills, hard. I do not pretend to say that this is the only reason why the natives of this locality have stone, but it is one of them, and, I am inclined to think, the principal one.

Very respectfully,

F. Carrow, M.D.

Wilmington, Del., March 4, 1884.

COMPENSATION FOR EXPERT TESTIMONY.

To the Editor of The Medical News.

Sir: In your editorial of March 1st, on "Compulsory Expert Testimony without Remuneration," you state that Iowa alone has secured justice to the expert through legislation, which, while technically correct, does not adequately represent the present status. The Supreme Court of Indiana, in 1878, declared the right of the expert to compensation. In the same year, Judge Clark, in the "State of Texas *vs.* Jasper Weathers," maintained the same right. In 1877 a Circuit Court of West Virginia did the same, while the Supreme Court of Alabama took the opposite view, which probably accounts for the action of the Greene County (Alabama) Medical Society. In Ohio, the Common Pleas Court of Madison County in April, 1882, of Franklin County in June, 1883, and doubtless others, have established the precedent of awarding experts reasonable compensation. It is a question whether judicial decisions are not a better security for justice in this matter than legislative acts.

While writing on legal topics, I would also call your attention to an error in the last sentence of the Cincinnati correspondence in the same number. The law already is compulsory, declaring that the superintendent of an infirmary, etc., *shall* deliver the body on the written requisition of a professor of anatomy. There has been no difficulty in getting a supply of material in Columbus since the passage of the Anatomy Act, but as long as Cincinnati maintains *five or six* medical colleges, no law is likely to give them a full supply.

Respectfully yours,

Henry G. Landis, M.D.

Columbus, Ohio, March 1, 1884.

NEWS ITEMS.

BERLIN.

(*From our Special Correspondent.*)

The Koch Mission, Fifth Report.—Following the preliminary and less interesting communications the

fifth report of the Cholera Commission is just received, and proves to be of the greatest importance. As THE MEDICAL NEWS will give a complete translation of it, I only send you the concluding passage, which might destroy a good many preconceived opinions still existing in America, and therefore ought to be published as early as possible. It runs as follows:

"I learn from the medical journals, that the French Commissioners, who had been sent to Egypt for the exploration of the cholera, declare in the report given by them, that they have gained different results from those communicated by myself, having found organisms in the blood, which, according to their view, are peculiar to cholera. Since hereafter it might give the impression that the researches of the German Commission were being prosecuted in the wrong direction, I think it necessary to explain to your Excellency my opinion concerning the above statements.

"In the blood of the healthy man—besides red and white blood-corpuscles—there exist in varying quantity small, roundish, pale elements, the so-called blood-plates (Blutplättchen). In some febrile diseases, typhus fever and pneumonia for instance, these elements are greatly multiplied, and in consequence of their resemblance to micro-organisms have been repeatedly taken for bacteria. In the blood of individuals suffering from cholera, and of those who have died from that disease, they are likewise almost regularly multiplied, as we were able to verify in the cases of cholera examined. This fact, after all, is not a new one, since it has been already mentioned by former examiners. D. D. Cunningham, for instance, as early as 1872, in his *Microscopical and Physiological Researches into the Nature of the Agent Producing Cholera*, has given a very good figure of these formed elements of the choleraic blood.

"Now, since even the most approved methods fail to recognize in the cholera blood any other elements similar to bacteria, and since the description given by the French Commissioners in every respect corresponds with the above-mentioned 'blood-plates,'[1] I cannot but conclude that the French Commission, falling into the same error as other examiners before, has taken the 'blutplättchen' for specific organisms. Any etiological connection with cholera cannot be ascribed to these blood-plates, since, as I have already mentioned, these elements are also met with in the blood of healthy individuals, and of persons suffering from other diseases."

Cutting criticisms have never been expressed with more gentleness and directness.

As for the rest of the report, its statements again merely confirm the observations made in Egypt. Pure cultures of the bacilli constantly met with in the intestinal walls and in the stools of uncomplicated cases of cholera, have proved that these bacilli are gifted with constant qualities characterizing their shape and their mode of growing in nourishing gelatine, whilst these characteristic elements were invariably absent in other diseases. The choleraic material was taken from nine post-mortem examinations and eight clinical cases.

In addition, interesting remarks are made on the influence of the new well-water supply in Calcutta on the decrease of the cholera mortality. The water was found to be of a very good quality. Hearty thanks are given to the British authorities for the lively interest shown in the work of the Commission, and the active support rendered in that city.

Everybody who had the honor of Dr. R. Koch's personal acquaintance, knew full well from the beginning that no vague theoretical suggestions would emanate from him, and the fifth report of the German Commission cannot fail to persuade even the most sceptical minds of the entire reliance to be placed on the statements which he has made.

DR. KOCH, in his fifth report, dated Calcutta, January 7th, and just published in the *Deutsche med. Wochenschrift*, Feb. 14, 1884, states that between December 16th and January 7th, nine autopsies were made, and material has also been obtained from eight cholera patients. The cases succeeded each other in tolerably regular order, so that there was ample time for investigating each. Several cases which, after a short and entirely uncomplicated course, proved fatal, were examined very soon after death.

Microscopical examination showed, in all these cases, the presence of the same bacilli in the intestines as were found in Egypt. In the report of September 17, 1883, the suggestion was thrown out that possibly these bacilli might be, as are so many other bacteria, regular parasites of the human intestine, and not peculiar to the cholera patient, and at that time distinguishing characteristics were wanting. This difficulty, however, has now been fortunately removed. Attempts to isolate the cholera bacilli and to make cultures have succeeded. Close observation of these cultures has brought out some very characteristic properties as to their form and their growth in gelatine, by which they can be recognized with certainty from other bacilli. It now remains to be determined whether these bacilli may be generally found in the intestine, or whether they are exclusively confined to the intestines of cholera patients.

In the first place, by means of gelatine cultures, the bacilli were demonstrated in the dejections of cholera patients and in the contents of the intestines of cholera corpses, and this was the case in all the observed cases; while in the contents of the intestines of bodies dead from other diseases, the bacilli of the choleraic intestines were not found. Up to this time eight bodies of persons dead of pneumonia, dysentery, phthisis, and kidney disease have been examined. Furthermore, the intestinal contents of different animals, and other substances rich in bacteria, were examined, but no bacteria resembling cholera bacilli were found. If these bacilli with specific properties are entirely confined to the cholera process, then there will scarcely be a doubt as to the relation between this process and the appearance of these bacteria, even if attempts to reproduce the disease in animals have not succeeded. Still, recent experiments of this kind have been so far satisfactory that we have reason to expect further favorable results.

The Commission has also studied, as far as possible, the relations of cholera to the City of Calcutta. It is only in the cities outside of India, which have been affected with cholera at long intervals, that the influence exerted on cholera by sanitary improvements, such as

[1] The readers of THE MEDICAL NEWS have been made well acquainted with these blood-plates by the excellent article of Prof. Osler, in the last number of the year 1883, page 701.

good drinking water, drainage, and the like cannot be determined with certainty. On that account every regulation should be carried out in the cities which, like Calcutta, have a considerable yearly cholora mortality. Previous to 1870, the average yearly mortality of Calcutta from cholera was 10.1 per thousand. Since 1870 it has fallen to 3, or more than threefold. It is to the improvement of the sanitary condition, and the bettering of the water supply especially, that these cities must hereafter look for an escape from cholera. The Commission has, to this end, inspected the water works and the canals of the city. They have also made a number of analyses of the river water, both before and after filtration in the water works of Pultah, and of the drinking water in the city.

United States Board of Health.—At the recent meeting of the House Committee on Public Health, a substitute for the National Board of Health's bill, "For the prevention of the introduction and spread of contagious and infectious diseases," was presented. The substitute provides for the formation of a United States Board of Health, composed of the Surgeon-Generals of the Army, Navy, and Marine-Hospital Service, gives the quarantine work to the Treasury Department, and the investigation into sanitary matters to the Navy, through its Museum of Hygiene.

The Surgeon-General of the Navy.—The President, on the recommendation of the Secretary of the Navy, has appointed Surgeon Gunnell to succeed Surgeon-General Wales as Surgeon-General and Chief of the Bureau of Medicine and Surgery of the Navy.

Surgeons J. S. Billings and J. S. Brown, U. S. A., have been detailed to attend the International Health Exhibition which meets at South Kensington in May next, and to represent the Department at the International Medical Congress which will convene at Copenhagen in August next.

The Investigation into Adulterated Dairy Products is being pressed upon the attention of Congress, and the House Committee on Public Health has already given the subject some attention. A resolution has been referred to it which will open up the whole subject of oleomargarine, suine, butterine, and other imitations of butter.

Yellow Fever at Havana.—There were six deaths from yellow fever at Havana during the week ending February 23, 1884.

Sanitary Council of the Mississippi Valley.—The Sixth Annual Meeting of the Sanitary Council of the Mississippi Valley will be held in the city of Memphis, Tenn., on Wednesday, March 19, 1884.

A Case of Mistaken Sex.—The case of mistaken sex reported by Dr. Wm. P. McGuire, of Winchester, Va., in The Medical News of February 16th, has attracted widespread interest. We learn that since the publication of the article, the party has married, and he reports to Dr. McGuire that he has regular sexual intercourse with ejaculation of semen, which, owing to the position of the external opening of the urethra, does not fall into the vagina. With this exception, both parties maintain that the act of coition is complete.

Tattooed Woman Bearing a Tattooed Child.—A paragraph has been going the rounds of the newspapers for the last few days, to the effect that a tattooed woman who has been exhibited in most of the large cities, had given birth to an infant bearing marks on its body similar to those on its mother's. We are informed by Dr. A. T. Shertzer, of Baltimore, who attended the woman in her confinement, that there is no truth in the statement, and that the infant bears no unusual marks.

The American Journal of Ophthalmology.—Dr. Adolf Alt, of St. Louis, Mo., announces the publication of a monthly journal under this title, the first number of which will be issued on April 15, 1884.

Commencement of the University of Louisville.—At the Annual Commencement, held on Thursday, February 28th, the degree of Doctor in Medicine was conferred upon eighty-four candidates. Prof. J. A. Octerlony delivered the Valedictory Address.

College of Physicians and Surgeons, Baltimore.—At the Twelfth Annual Commencement of the College of Physicians and Surgeons, held on March 4th, the degree of Doctor in Medicine was conferred upon one hundred and twenty-seven candidates.

The New York Post-Graduate Medical School and Hospital.—The new building occupied by the above school and hospital, has a frontage of ninety-five feet on East Twentieth Street, and is four stories high above the basement. In the latter are situated the drug department and the general waiting-room for patients, together with a number of rooms used for dispensary purposes.

On the first floor are a large and well-lighted lecture-room and examining rooms for the several departments, and also the office and a handsome and well-equipped reading-room.

On the second floor are class-rooms assigned to the different chairs, and in which practical courses are given to classes limited to a certain number of students. Some of these rooms are fitted up with costly apparatus and appliances.

The third floor is devoted entirely to hospital purposes.

The fourth floor is used partly for hospital purposes and partly for the accommodation of the employés. On this floor there are also two rooms fitted up by Prof. Roberts for photographic purposes, and furnished with a skylight, etc. For greater convenience as to light, the pathological laboratory is also on this floor.

In a detached building in the rear, are the mortuary and the rooms for practical anatomy and operations on the cadaver. Accessible by a separate entrance is an accident ward for the reception of emergency cases.

Taken as a whole, the building is thoroughly adapted for the purposes to which it is applied. The location is central as regards the principal hospitals and dispensaries, and is accessible from all parts of the city by means of elevated and surface railroads.

The New York Skin and Cancer Hospital.—The position made vacant by the resignation of Dr. Hunter

has been filled by the appointment of Dr. J. E. Janvrin, with Dr. J. R. Goffe as his assistant.

INTERNATIONAL OTOLOGICAL CONGRESS.—The next International Otological Congress will meet at Basle, on September 1st and continue until the 4th. A detailed programme will be issued about June 1st. Communications should be addressed to M. Le Dr. Burckhardt-Mérion, at Basle.

THIRD CONGRESS OF INTERNAL MEDICINE OF BERLIN.—This Congress will be held on April 21st to 24th, under the presidency of CH. FRERICHS. The following are the subjects for discussion: *First day*, Pneumonia. *Second day*, Poliomyelitis and Neuritis. *Third day*, Nervous Dyspepsia. The following communications have been announced: Hermann Weber, Hygiene of English Schools, considered especially with Regard to Contagious Diseases. Rosenthal, The Reflexes. Goltz, Localization of Cerebral Functions. Pfeiffer, Vaccination. Siegen, Diabetes. Rossbach, Treatment of Infectious Diseases; New Applications of Naphthaline.

PROFESSOR TARNIER.—By a decree of February 5, 1884, M. TARNIER has been appointed Professor of Obstetrics and Diseases of Women and Children, in the Faculté de Médecine of Paris.

PROFESSOR FRERICHS.—The Russian Government has conferred on Professor Frerichs the Grand Cordon of S. Stanilaus, in recognition of his services in connection with the education of Russian students in the Universities of Breslau and Berlin.

SIR SPENCER WELLS IN ITALY.—Sir Spencer Wells, who has been making a short stay in Italy, has been received by his Italian confrères in Rome and Naples in a very cordial and gratifying manner. At Naples he was publicly addressed by Professors Schrön and D'Antona, and by the students.

YELLOW FEVER AT RIO JANEIRO.—The Consul General at Rio Janeiro has sent to the State Department, a tabular statement showing the number of deaths at that place from yellow fever, from the year 1850 to 1883 inclusive. It is too elaborate to reproduce here, but an examination of the table indicates that the disease was more fatal in the following years: 1850, 4160 deaths; 1852, 1943 deaths; 1857, 1425 deaths; 1860, 1249 deaths; 1870, 1117 deaths; 1873, 3467 deaths; 1875, 1291 deaths; 1876, 3317 deaths; 1880, 1573 deaths, and 1883, 1494 deaths. No deaths occurred from the disease in 1855, 1856, 1858, or from 1863 to 1869.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending February 23, 1884, indicate that rheumatism, diarrhœa, intermittent fever, influenza, pneumonia, whooping-cough, and bronchitis have increased, and that inflammation of the bowels and measles have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending February 23d, and since, at ten places, scarlet fever at twenty-three places, and measles at ten places. One death from trichiniasis was reported at Niles Feb. 22d.

OBITUARY RECORD.—DR. ROBERT THOMAS COLEMAN died in Richmond, Virginia, on March 4th, æt. 53 years. He graduated in Medicine from the University of Virginia in 1850, and in 1851 received the degree of M.D. from the Jefferson Medical College, Philadelphia. He then entered the Philadelphia Hospital as an interne, where he remained for two years, and returned to Richmond in 1854. In the autumn of this year, when the hospital was converted into a school for clinical instruction, the Board elected him lecturer upon clinical medicine. This honor was declined, and he remained in Richmond until the outbreak of the war. After entering the Confederate Army, he was rapidly promoted to the grade of Brigade-Surgeon, and was made Chief Surgeon of the Stonewall Division, when that body was organized. He was twice temporarily detached from his division to act as President of the Commission of Inspection, being in this position second only to the Secretary of War. In 1865 he was elected Professor of Obstetrics in the Medical College of Virginia, which position he held until his death.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 26 TO MARCH 3, 1884.

BAILY, J. C., *Major and Surgeon.*—Granted leave of absence for one month, to take effect on or about March 1, 1884, with permission to apply to the Adjutant General of the Army, through Division Headquarters, for an extension of three months.—*S. O. 24, Headquarters Department of Texas*, February 26, 1884.

BENHAM, R. B., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort A. Lincoln, D. T., and ordered to Fort Sisseton, D. T., for duty.—*Par. 1, S. O. 22, Headquarters Department of Dakota*, February 26, 1884.

PHILLIPS, JOHN L., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Warren, Massachusetts.—*Par. 2, S. O. 39, Headquarters Department of the East*, February 28, 1884.

FISHER, WALTER W. P., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at the Presidio of San Francisco, Cal., from 18th inst.

POLHEMUS, A. S., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Winfield Scott, Cal., from 18th inst.—*S. O. 23, Par. 1 and 2, Headquarters Department of California*, February 21, 1884.

DIETZ, WILLIAM D., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at U. S. Military Academy at West Point, N. Y.

PHILLIPS, JOHN L., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty in Department of the East.

MEARNS, EDGAR A., *First Lieutenant and Assistant Surgeon.*—Assigned to duty in Department of Arizona.

KNEEDLER, WILLIAM L., *First Lieutenant and Assistant Surgeon.*—Assigned to duty in Department of Dakota.

BLACK, CHARLES S., *First Lieutenant and Assistant Surgeon.*—Assigned to duty in Department of Texas.—*S. O. 46, Par. 1, A. G. O.*, February 25, 1884.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ORIGINAL LECTURES.

ANÆMIA AND ITS RELATIONS TO THE SEXUAL ORGANS.

A Clinical Lecture delivered at the Long Island College Hospital.

BY ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF GYNECOLOGY, AND SURGEON IN THE LONG ISLAND COLLEGE HOSPITAL.

(Reported by Edward Develin, M.D.)

GENTLEMEN: To-day I call your attention to the subject of anæmia, the relation it bears to the various derangements of menstruation, and the abnormal conditions of the female sexual organization.

Case I.—The first patient, which I here present to you, is twenty years of age. She brings with her, almost, the diagnosis written in her personal appearance. There is an exceedingly interesting chapter in medicine classed under the head of the physiognomy of disease. It is quite surprising how any one, who has taken the time and trouble to acquire the faculty of reading its pages, can detect the different symptoms of disease when looking at the patient. Now, at a glance I see that for one of her age she is undersized, that there has been a general arrest of development to a certain extent; one, however, may be very complete in all proportions, the organization may be as perfectly well developed in those who are of undersize as those who are of medium size; so that the fact of being below the average size does not necessitate lack of power or endurance. We have only to call to mind such men as Napoleon in confirmation of this statement. Therefore, if small stature exist alone, it stands for nothing. But this patient has the physiognomy of disease, and when I tell you she is anæmic, you will doubtless have anticipated the statement. But it is not enough to look at a pale face to base the diagnosis of anæmia upon, because we sometimes have the capillary circulation deficient, and although the patient may look pale and almost waxy, there may be no anæmia present. It may be more a defect of capillary circulation in the cheeks. But there is one point that is almost always infallible, and that is, pallor of the mucous membranes. When we find these pale, we have the physiognomy of disease. I find here the conjunctiva on both sides is perfectly anæmic, the tongue has that peculiar appearance, and so have the lips. We have here all the well-marked symptoms of anæmia; the pulse is extremely anæmic, in fact, she has to some extent the physiognomy of chlorosis. It is, however, necessary to have more than anæmia to have a chlorotic diathesis. This patient also has the peculiar color of hair that occurs in this temperament of females. She has not as much adipose tissue as is usual, but still she is not emaciated. On examination, I distinguish the bruit or murmur of anæmia which occurs with the first sound of the heart, giving us the most marked evidences of anæmia.

Next in order comes the question, What is the cause of this condition? Is it congenital? It may be so. I have seen plenty of chlorotic children. The question is, Is this entirely congenital? if I may be pardoned the term. Is it natural to her, or is it acquired? I find that she has a small circulatory apparatus; in chlorotic patients we have the small heart and bloodvessels almost always connected with an imperfectly developed sexual system; the mammary glands, however, are generally well developed. Such cases we often find with a malformation of the uterus, such as flexion or an infantile uterus; consequently, we have amenorrhœa, or dysmenorrhœa, with all the derangements of the sexual organs which arise from this imperfect development.

This patient informs me she has always been pale; she commenced to menstruate when she was sixteen; has always suffered great pain during menstruation, so much so that she is compelled to keep to her bed, the flow lasting but three days. Her menstruations again, we find, have been very irregular, sometimes five weeks intervening, and on one occasion seven months; always going beyond her time; has never fallen short. The pain, she states, commences a day or so before the flow begins, but as soon as this commences the pain is somewhat relieved.

This is almost a typical case of chlorosis, although there are some points to which I shall call your attention, and which might be better marked. In this case it is not necessary to make a physical exploration of the sexual organs, although in case we fail to relieve by therapeutic measures, then we will examine for the local cause of this dysmenorrhea. I shall, however, venture to give you the physical signs usually found in a case of this kind. You would find that the uterus does not measure, in its long diameter, two inches; in the next place, the vaginal portion of the cervix is not larger around than my little finger; the measurement of the uterus from before backward is even less than an inch, and is flexed either backward or forward. If this uterus were removed from the body, and held by the end of the cervix, between the thumb and finger, it would fall over; a normal uterus will, to use the expression, stand alone, when removed from the body. The ovaries also may be illy defined, but that is a question; the probability, however, is that they are small. If the ovaries be well developed, it is surprising how they will insist upon the uterus performing its functions to the greatest possible extent of its power; we thus find that the menstruation may be conducted in a proper manner though the uterus be undersized. In the case before you, the menstruations are irregular, the time intervening being abnormally long.

The question is, What can we do? Not much at the age of twenty; had we seen her earlier, we could have secured more complete development of the entire organization; we can now only try to overcome the consequences, and put her on the most nutritious diet and tonic treatment.

I have just asked her the question, if she works in to-

bacco? and her reply was, yes. I mention this because she has that peculiar appearance around the nails of the fingers which is observed in those who are employed in this manner. I cannot explain the character of this appearance, but I have noticed the strong tendency of this nicotine poisoning to produce most marked anæmia.

In the chlorotic patient there is a tendency to the development of a markedly profound anæmia, owing to the fact that the blood-making power of such an organization is defective. So this little girl starting out in life with an imperfect organization, has suffered very much from her conditions of life, especially her occupation in the tobacco factory. And so she is more anæmic now than she has been at any time in the past. We can, however, improve all this by general tonic treatment, including the chalybeates, and bring her up to the highest standard of health possible with such an organization. This will be the extent of our ability in this case.

Case II.—This patient I have presented to you at a previous clinic; she comes here to report progress. She is eighteen years of age; her catamenia occurred two years ago; she then menstruated regularly for five successive months, after which time the menses ceased, and did not return for one year and seven months. She came under our care delicate and anæmic; it was then pronounced to be a case of amenorrhœa, due to general debility and anæmia. Acting upon that principle, she was placed upon restorative treatment; as you observe, the tongue is now perfectly clean, and, as I have just stated, she menstruated one week ago for the first time in nineteen months.

This is a very satisfactory case, as it illustrates what we so frequently see, viz., that these cases of amenorrhœa due to general debility and anæmia, will respond to treatment remarkably well, if you adopt the proper course, bearing in mind that the cause of the amenorrhea is the depressed condition of the general system. Such cases as these when properly and effectively treated, give you a reputation in your profession; to be able to restore the glow of health and color to the cheeks and lips, and restore the lost function of the sexual organs, is gratifying alike to patient and physician.

Case III.—This young lady is twenty-four years of age, and was born in Nova Scotia. She first menstruated when seventeen years old, the periods being at first from two to three months between; menstruation is, however, now regular, lasting for three days. She comes here complaining of pain in the lower portion of the back; this, however, is not constant, and may be brought about by stooping or lifting. She does not always have this pain during menstruation; the bowels are now regular, although at one time she suffered from constipation.

The question to decide is, whether there is any special trouble with the pelvic organs which gives rise to the pain of which she complains. I hardly think there is anything which especially calls for local treatment. I think, however, we can build up her general health, and by this means relieve her sacral pains, which are almost always due to disease of the pelvic organs; but not so in this case. Now here is a case which might deceive you if you were not on your guard; you notice that she has a particularly healthy color; the capillary circulation in her cheeks is remarkably active; she is, however, not strong or plethoric; her pulse is weak; she has no more strength than the little pale patient you have just seen.

Another point of interest is that she did not menstruate until she was seventeen years of age; but then we must remember that she was born in a colder climate than ours, so that this function was not, under the circumstances, abnormally retarded. The facts in her history show that her trouble is general, not local, hence we shall let her sexual organs alone, and build up her general health.

Case IV.—This patient you will doubtless remember having seen at one of our previous clinics. She then stated that she was seventeen years of age and had not yet menstruated. After running over her case, noting her size and general lack of development, we came to the conclusion that, though old enough, she was not, however, developed sufficiently to menstruate: that her conditions of life had been such as to retard her menstruation. Therefore her amenorrhœa was conservative. She did not menstruate, simply because she was not able to do so. I dwelt at some length upon how important it was to ascertain the cause giving rise to this amenorrhœa; whether it was due to malformation, arrest of development, either general or local, or an impaired condition of health. In this case we decided that it was due to her general lack of development, and we therefore directed our attention to her general organization, leaving out entirely her pelvic organs, putting her upon constitutional treatment only.

Dr. Cushing, under whose observation she has been, then placed her upon tonic treatment, and has the satisfaction of knowing that she menstruated for the first time just three weeks ago. The tongue and lips, you will here observe, are of a more healthy color, while there appears the glow of increasing health in her cheeks. She has also some warmth now in the hands, which before were cold and damp. The treatment here has been faithfully followed out, and, as you can all perceive, with the most satisfactory results.

Case V.—This young girl is twenty years of age; she informs me that she commenced menstruating when fifteen years of age; she has always been irregular in her menstruations, going from four to eight weeks. During this time she has frequently suffered from a profuse leucorrhœal discharge; this, however, has been relieved by the hot-water douche. The bowels are also habitually constipated. She comes here to-day complaining of severe pain, mostly in the left iliac region, this pain commencing about a week before the menstrual flow and continuing for a day or two after the flow has ceased. A peculiarity of the pain is that it is not intermittent, as the pain of dysmenorrhœa often is. Then, again, the pain is not located in the region of the uterus. Keep this point in mind. This pain has gradually been getting worse with each succeeding menstruation. The patient has but little appetite, and is somewhat anæmic, although she has some color at present; this, however, is only temporary; her pulse is not strong, but still she is not chlorotic. She also complains of pain in the region of the stomach, which is increased upon eating.

Now from the occupation of this girl, which is that of a milliner, we might expect such a condition as we have here, resulting from the constant stoop of the body while

at her work, which retards the portal circulation and keeps the pelvic organs engorged. There are also indigestion and constipation, which arise from these sedentary habits. Now this dysmenorrhea is what I wish you specially to remember, because it is not uterine. I presume her uterus is not at fault, although no physical examination has been made; neither is there any reason for us to do so. Dr. Stewart, under whose treatment she now is, believes that he can cure her without local treatment, and when that is at all possible, it is much better to adopt this plan. I consider it something akin to malpractice to make these physical investigations where there is no local trouble; it is a terrible ordeal for a young girl to submit herself to a physical examination, and it is only justifiable when it must be done. It is a great blunder to investigate these cases on a mere supposition, and I always avoid it when possible. Now, as I have told you, the pain is not in the region of the uterus, but in the region of the ovary and upon the left side; and, by the way, we find that the left ovary is more often the seat of inflammation than the right; then again, the pain commencing a week before the menstrual flow is a symptom which occurs in most cases with great regularity in those suffering from ovarian disease and painful ovulation. In nineteen cases out of twenty presenting these symptoms, you will be safe in making a diagnosis of ovarian trouble; you may not be able to say what the exact pathology is, although it is in all probability inflammatory or hyperæmic, when you have these painful ovulations. If this were a married lady, we could make an examination without outrage to her feelings; we should then find that the ovary was tender to the touch. The ovary in its normal condition will bear a certain amount of pressure, but in this case it would probably be quite tender, and by reflex action might produce nausea. This is the condition of things we find described under ovarian dyspepsia by some of the English authors, more especially within the last year or two by Fothergill, who gives an illustration of these cases. I have no doubt that this girl's trouble is ovarian. You will find in these cases that the menstrual period is irregular, because the uterus is under an abnormal ovarian influence.

I am one of those who believe that the ovaries are the main factors of the whole problem of menstruation; that they give the initial influence; and that they are the primary and most important structure of the sexual system, and, therefore, that menstruation is governed by the ovaries; hence, in disease of the ovaries the menstrual periods become irregular. This leucorrhœa from which the patient suffers, is relieved by injections, and when that is the case it is probably vaginal and not uterine; I have never yet seen uterine leucorrhœa relieved by an injection. I have no doubt the vaginitis is the source of her leucorrhœa, that is very common in such cases as this where the occupation of the patient compels her to bend the body forward, this position interfering with the return circulation.

We have also vaginitis in those who are below par in general health. The mucous membranes becoming relaxed assume an abnormal condition, especially in those of a strumous diathesis. Now in place of annoying this uterus, which is probably behaving as well as it can under its present influence, we shall direct our attention to relieving her vaginitis, and build up her general health, and thus try to relieve the ovaries. If she be restless at night, give her a little bromide to induce sleep, and, by and by, perhaps a little counter-irritation; also directing her to lie down during the day at intervals if possible, and so remove pressure from the ovaries and secure free circulation; so gradually guiding her along in this way to relieve that ovarian hyperæmia. This, I have no doubt, will afford her great benefit.

This case is extremely interesting for you. See what miserable work you would make of it if you were to direct your attention to the uterus. Suppose you were to give her emmenagogues when she was menstruating; you would simply increase the hyperæmia of her pelvic organs, and only make her worse. You thus see how important it is to find the cause of the difficulty from which this girl is suffering.

Unfortunately, our books have not sufficiently dwelt upon this form of deranged menstruation. I have seen cases of amenorrhœa, dysmenorrhœa, and this irregular menstruation treated by vigorous measures directed towards the uterus when it was not at fault, the disease being ovarian, as in this case. This is a point I desire you to bear in mind. When you have this pain in the left side, especially when it is aggravated by defecation, as it usually is, owing to the peristaltic action of the bowels, you may know that it is in all probability ovarian. As a proof of this, Dr. Stewart informs me just now that, when she is not suffering from constipation, the pain is considerably relieved. This case illustrates a derangement of menstruation which gives something of the same history as the cases of anæmia, but from another cause.

A NEW METHOD OF TREATING LARGE BONE CAVITIES IN THE LOWER END OF THE FEMUR IN ADULTS.[1]

By F. LANGE, M.D.,
VISITING SURGEON TO BELLEVUE HOSPITAL, NEW YORK.

Though in young persons, as a rule, no considerable difficulty is experienced in healing large bone cavities, I have repeatedly experienced with adults, after extensive operations in the lower part of the diaphysis of the femur, a very obstinate condition with reference to complete recovery. Those large bone cavities are, sometimes, not filled up by tissue of permanent existence. Fistulæ remain which, perhaps, after a longer time of careful treatment, show a tendency to heal, but after some exertion or traumatism or constitutional disturbance are apt to open again under renewed suppuration; and though not often, still in some cases, after long years of more or less suppuration and attacks of inflammation, amyloid degeneration, with its fatal consequences, occurs.

In looking carefully over hospital records, one hardly ever fails to find recorded cases of one or the other of these varieties; the majority of them, probably, at last staying away from hospitals, be-

[1] Read before the New York Surgical Society, February 26, 1884.

coming tired of medical treatment as well as of their doctor.

In the three cases which I shall now present I have tried, by means of a plastic operation, to obliterate entirely the bone cavity. The operations consisted, with slight modifications, in forming an anterior flap from the soft parts covering the lower end of the femur, which has its base either corresponding to the articular line or laterally. Then, in our cases, where ankylosis existed in the straight position, the patella is extirpated and the whole anterior wall of the bone cavity is taken away. Finally, an oblique section is made, severing the anterior third of the condyles and descending toward the bottom of the bone cavity. In this way the abruptness of its lower edge is replaced by a smooth, oblique plane. The whole bone cavity must be most thoroughly scraped out and disinfected. I should recommend that a spray of a disinfectant solution should be forced against the bone surface from a short distance. Nothing like that gives such a thoroughly clean bone surface. Then the dorsal flap, whose length must correspond to the extent of the cavity, is depressed toward the bottom of the cavity and eventually fastened by a nail or needle. No sutures are applied. Of course raw surfaces remain above the edges of the flap, which are left to heal by granulation. It is remarkable how the great difference of level, existing in the beginning, disappears in the course of months. By and by that flap is raised again. It seems as if new formation of tissue, probably of a bony nature, takes place below it. I was led to practise this plan by a similar method practised and recommended by my friend, Dr. Neuber, on the head of the tibia. So far as I know, no similar operation has been performed on the lower end of the femur.

All of our three cases are very interesting. They occurred in women of from thirty-eight to forty-six years of age. All of them had a serious osteitis on the lower end of the femur above the epiphyseal junction some twenty-five to thirty-five years ago. None of them underwent any operation at that period, at least no operation by which the bone has been touched. In two, small particles of bone came away spontaneously, and that, in one of them, more than twenty years after the first attack. All had long intervals of fifteen or more years of health with a comparatively useful limb until, in one case from constitutional disturbance after childbirth, in the other two cases from traumatic causes, renewed inflammation took place at the original point of lesion. In all of them large cavities existed in the lower end of the diaphysis, the classical seat of osteomyelitis in young persons. In no case did these cavities contain any dead bone; but granulations, here and there broken down, so that pus lacunæ were formed. Toward the periphery small spiculæ of bone were found scattered between those granulations, but all the cancellar tissue was softened, rarefied, pervaded by granulations and small abscesses. The cortical substance was, to some extent, implicated also. The sharp spoon, without any great force, found a cavity which extended beyond the limits of the healthy bone. Finally it was arrested by a hard, sclerotic shell. The epiphysis, in all of these cases, was in a state of advanced fatty degeneration, but not pervaded by granulations.

In the upward direction, in all of these cases, there was no distinct boundary towards the medullary canal, at least no bony diaphragm—which is the rule in those standard bone abscesses, which, I think, clinically and pathologically, require a different conception from those just described. Not long ago, I presented to this Society a case of bone abscess in the lower half of the femur. The patient was about twenty-seven years of age, and his history was very similar to that of to-day's patients. In his case, however, the bone abscess was narrow, long, consisting of many small, lengthy pus lacunæ, and reaching almost as far as the middle of the femur. The cortical substance was enormously thickened, and a very small particle of dead bone was found within the cavity. The nature of this case was, I think, exactly the same as in these cases: but the process of new formation of bone was much more active, while the granulating process within the medullary spaces was not so active as to lead to formation of a large cavity at the expense of preëxisting bone tissue. Essentially, however, the contents and walls of this cavity were of the same nature. It seems to me that these cases must be differentiated from those bone abscesses which, within a smooth sclerotic bone cavity, covered by a rather smooth pyogenic membrane, contain a peculiar, creamy pus.

Let me mention that all these patients were born in those regions in which acute osteomyelitis is more frequently observed; one of them from Switzerland, the two others from the lowlands of Northern Germany.

Case I.—Mrs. P., forty years of age, born in Switzerland, from a healthy family. Had severe "typhoid fever" in her twelfth year, after which she was reduced for a long time to a state of considerable physical feebleness. During this period, and several months after the first-mentioned disease, she fell on her feet from about four to five feet, followed by pain in her knee. This left her for a short time; but, however, it very soon, during her day's work, returned with great severity. A severe inflammation of the bone followed, accompanied for a long time with pain and fever, till, after long application of poultices, an abscess broke above the knee, on the median and lateral aspect of the femur. A great deal of pus escaped, and, later on, several small particles of bone. After about half a year's duration, the process was healed. By and by the limb became useful, and remained so, except that she suffered from what she called "slight rheumatic" pains. There was no ankylosis. She married in her nineteenth year, and had had eight normal births.

In May, 1880, patient fell from a staircase, and received a severe blow against the left knee; was laid up with pain and swelling. About six weeks later, in middle of July, I saw her in consultation with Dr. Hueler. At that time there existed an extensive suppuration in and about the knee, which required a good many incisions. It was found that

the patella was broken, and that a kind of diaphragm passed from the seat of fracture near the upper edge of the patella toward the condyles, thus separating the upper recesses into two cavities, both of which were filled with matter. After about four or five months, patient was again able to walk, with stiff limb, a fistula remaining at the anterior aspect, somewhat above the internal condyle, and another at the outer aspect corresponding to the lower edge of the external condyle. The knee was in hyperextension, and an abnormal lateral mobility remained for a long time. The sinus led toward the joint, in a downward direction. The lower end of the femur was all the time thickened, the soft parts tense and immovable, but not particularly painful on pressure.

The history of the following two years, during which time the patient was not treated by me, is in short this: the sinus showed tendency to heal, but then with increasing pain and swelling, and absolute powerlessness for weeks, ample discharge occurred, after which the limb returned to a more normal condition. At last the patient consented to a renewed operation, which I had proposed years before, assuming that the real seat of the suppuration must be in the lower end of the femur, and I did it on the 27th of April of last year, in a way similar to that described.

The fractured patella did not offer any peculiar interest. A large cavity occupied the lower end of the thickened femur. It was laid open freely. A fistulous tract led through the obliterated joint between the condyles to the posterior surface of the femur. The fistula on the outer aspect communicated with that. The bone here was also softened and in a state of rarefaction. A good deal of it was gouged away. The soft parts on the anterior aspect were not so intimately depressed into the anterior deep bone cavity, nor was that possible, because in this case I had not yet made the horizontal section of the anterior portion of the condyles. The lower edge of the cavity, therefore, was too abrupt. Gradually complete recovery took place, not, however, without a slight attack of retention about three months after the operation. Still the soft parts, by the process of cicatrization, seemed to have been gradually drawn into the cavity. The limb is completely ankylosed, but reliable and useful. After the operation about four or five months elapsed till cicatrization was complete.

CASE II.—Mrs. B., forty-six years of age, from a healthy family, had in her seventeenth year a severe inflammation, preceded by rigor, above the right knee. The left one was also affected in the beginning, but improved spontaneously. After ten weeks of fearful suffering, an ample discharge of pus occurred above the internal condyle. The wound closed itself after several weeks, broke again after the first trials to walk, and then healed completely, and by and by the limb became useful. Flexion was somewhat impaired, and remained so. In 1870, she suffered from a lung trouble, which was thought to be consumption. During this time again appeared sudden pain in the previously affected limb, with rigors, redness, and swelling. After several weeks, an abscess broke about the old spot. No pieces of bone were discharged. Four months later, patient was able to walk again, but a fistula remained, and mobility grew worse and worse till finally the leg became quite stiff. In January, 1883, patient fell down stairs, was not able to take the necessary care after that, and very soon commenced to suffer again from severe pain above the knee-joint. On March 31st, I was called in consultation with Dr. Babier, and opened a large, apparently periarticular, abscess on the inner aspect, by two long incisions. Sinuses remained, with repeated attacks of retention, apparently due to an osteitic process within the bone. In September, the radical operation was done in the manner originally described. A large opening was found to exist on the anterior aspect of the femoral bone, tightly covered by the quadriceps femoris and upper edge of the patella. The cavity itself reached as far down as the epiphysis, which latter was in a state of advanced fatty degeneration.

Complete recovery took place in about three months. There is almost complete anchylosis. The patient is wearing a brace in order to promote stiffening. The limb is becoming useful and stronger. She is able to walk a few blocks, and improves every week.

CASE III.—Mrs. T., thirty-three years of age, had an acute osteitis in her thirteenth year, for which she was under medical treatment for seven months. An abscess broke, and a yellowish fluid was discharged. For the whole year subsequent to that the leg was stiff and flexed, and the patient was obliged to use crutches, but by using salt-water baths it became almost normal, flexible and useful. Fourteen years later the patient married, and four years after that she was delivered for the second time, that was in 1881. She had a protracted puerperium, with fever, and became much reduced in strength. Two months after that her thigh became inflamed; she was in bed for nine weeks; an abscess broke above the inner margin of the patella, and more of a serous yellowish pus was discharged. That healed, but after a short time renewed inflammation began. A fistula remained, the knee became quite stiff, but gradually could be somewhat used. In May, 1883, a small piece of bone was discharged, and in June, after a renewed attack of severe inflammation, another. In September I saw the patient and proposed an operation. The same was performed at Bellevue Hospital on the 3d of September. I confined myself to laying bare the fistulous opening which led into the bone on its anterior external aspect, corresponding about to upper edge of the patella. The tendon of the quadriceps had to be cut across. The opening was enlarged, and a large cavity scraped out, drained, and treated with the permanent antiseptic dressing. Everything went along nicely for about two months, when renewed retention and inflammation occurred. I then decided to do the radical plastic operation. This was done by my brother on the 28th of November under my directions. The defect of bone in this case was perhaps the largest of all. The

epiphysis was so much flattened and its cancellar tissue so rarefied that it broke under the chisel and was made smooth by means of a knife. The lower part of the diaphysis, the seat of the cavity, was very much thickened, but only a comparatively thin shell of bone remained, into which the large dorsal flap was depressed. Its point was fastened by a steel needle driven into the bone. Recovery has taken place in about ten weeks, and about ten days ago patient commenced to walk with a brace, in order to keep the limb entirely stiff and not allow of the slightest spring-like motion, which existed in this case as well as in that just presented.

The patella, as you see, shows on its rear surface osteitic thickening, and a carious surface just about that point, where, for a long time, it had been exposed to the influence of the inflammatory products.

It was peculiar to all of these cases that the opening into the bone cavity was on the anterior aspect, corresponding about to the insertion of the quadriceps femoris.

A CASE OF SARCOMA IN THE ANTERIOR MEDIASTINUM.

By EDWARD T. BRUEN, M.D.,
DEMONSTRATOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

A. N., a male, came under my notice in the Philadelphia Hospital in December, 1882. His family record was free from any history of malignant disease, and he had enjoyed good health until eight months before. His illness had been chiefly characterized by emaciation and pain in the chest. He was a tall, slightly built man, and when I saw him had evidently lost half his weight. The pain was most severe over the upper segment of the sternum, and radiated around the chest. There was dulness on percussion over the upper part of the sternum, and the respiratory murmur at the right border of the sternum was bronchial. The cardiac sounds, particularly the second, were almost inaudible. The remarkable feature about the above physical signs of percussion and auscultation was the localization of the pathological physical signs to a district scarcely more than four inches square at the upper part of the sternum; the dulness downward was continuous with the cardiac dulness. Elsewhere, throughout the lungs, the physical signs were normal. The pressure-symptoms were very few, principally consisting in some evidences of pressure on the venous trunks, such as lividity of the face, with enlargement of the veins of the upper part of the neck. The other viscera throughout the body were normal. The patient died from exhaustion February, 1883, worn out by pain, which increased with the progress of the case.

Post-mortem.—On removing the sternum and cartilages, they were found to be adherent upon the right side to a mass which occupied the anterior mediastinum. The growth was seven inches long, measuring from the sternal notch, and terminated in a somewhat diffused thickening of the visceral pleura, which covered the anterior margin of the upper and middle lobe of the right lung. The growth was sausage-shaped and about two and one-half inches broad. It overlaid the aorta, pulmonary artery, and the vessels of the neck, thereby compressing them, and accounting for the muffling of the cardiac second sounds during life. The point of origin of the growth was obscure; it was evidently unconnected with the anterior mediastinal glands, or with the thymus gland; some of the lymphatic glands at the root of the lung were slightly swollen, but not generally involved. The calibre of the trachea was not diminished. The glands of the neck were unaffected on either side. Laterally, at the lower portion of the growth, the pulmonary pleura was thickened at the line of contact with the growth, but the lungs were free from any traces of disease. The pericardial tissues at the right side of the chest were also somewhat thickened. The growth itself was of a fibrous consistence, of a gray-white color, and contained a softened tissue running through its centre. It was found, on microscopical examination, to be composed of medium-sized lymphoid cells, mixed with spindle-shaped cells, and imbedded in a homogeneous stroma, or a stroma which consisted of reticulated fibres and wavy fibrous tissue. The peripheral thickenings of the pleura and pericardium were made up of similar elements.

There are certain reflections, based upon the clinical history of these tumors, which may be profitably considered in this connection. The age of patients suffering from sarcoma is commonly less than in cancerous malignant growths. In *Virchow's Arch.*, Bd. xciii. Heft iii., the statement is recorded that in 7566 autopsies, 158 malignant mediastinal growths were observed; of these, 31 were cases of sarcoma, the average age of the greatest number of cases being 41 years. Twenty of these occurred in males, the average being 38 years; 11 in women, whose average age was 48.

One hundred and twenty-seven of the above (158 cases) were carcinomatous growths, 81 in men with an average age of 53 years; 46 in women, average age of 56 years. In the *Trans. of the Path. Soc. of London*, since 1866, five cases of mediastinal sarcoma have been reported—one by Fenwick in 1882, æt. 29, a male; one by F. S. Eve, æt. 20, in 1880. In 1872, E. Clapton and J. F. Payne reported a case in a male, æt. 37. In 1871, T. B. Peacock, one in a male, æt. 27; and in 1870 one in a male æt. 20 years, by R. D. Powell.

Sarcomatous tumors, however, sometimes occur in the aged, as, for example, a case of sarcoma involving the pericardium in a woman æt. 76 (*Virchow's Arch.*), and a case reported to the Philadelphia Pathological Society, January, 1884, by J. C. Wilson, M.D., occurring in a woman over 60 years old.

The majority of tumors of this character originate and are found in the anterior mediastinal region.

In 24 cases reported by Kahnlich (*Virchow*, Bd. xciii.), 13 occurred in the anterior mediastinal region, originating from the connective tissues therein, 5 from the periosteum of the sternum, 3 from amid the cervical glands, 2 among the bronchial glands, and 1 from the pericardial substance. The thymus, or thyroid glands, may also form foci of origin for

these growths. In the cases quoted from the *London Path. Soc. Transactions*, the origin of the tumors was invariably in the anterior mediastinum; in two of them, however, the posterior mediastinal glands were also involved. The invasion of the various intrathoracic organs in the above cases was chiefly by contiguity, and in general there seems little or no tendency to excite inflammatory action in their vicinity. The lungs were secondarily involved in all the cases to which I have had access, with the exception of two cases: the one reported in this article, and one reported by R. D. Powell, M.D., both of which are unique because the disease was localized only in the mediastinum.

It would seem that the growths in distant parts of the lungs follow the distribution of the lymphatic vessels, the principal site of secondary processes being in the connective tissues surrounding the minute bronchial tubes. It is an interesting fact that while the lung would seem never to be the site of primary sarcoma, yet the pleural tissues may be primarily involved. In the *Med. Record*, January 5, 1884, a number of cases are quoted from Lepine, Birch-Hirschfield, Böhme, Eppinger, and Schultz, and one by R. W. Greenish (*Journal of Anatomy and Phys.*), in which the growths were abundantly distributed in the pleural tissues as primary formations. The point of origin is believed by these observers to be either directly from the ordinary connective tissue cells or from the endothelium of the lymphatics.

In mediastinal sarcomata the glands of the neck are less commonly involved than when the process is cancerous.

The origin of cancerous growths in the mediastinal region is usually in the posterior portion. In contrasting the respective sites of these two morbid growths, we may expect the physical signs and pressure-symptoms to correspond with the location. The vessels of the neck suffer either directly from pressure or by being converted into rigid tubes, allowing of no adaptation to the amount of blood passing through them. The descending vena cava and bloodvessels of the neck are often dilated. The trachea is very liable to pressure, also the aorta, which is usually covered by the growth, and by being pressed away from the sternum, the sounds of the aortic semilunar valves, and those of the pulmonary artery, may be much reduced in intensity. Pressure-symptoms from an aneurism growing laterally, or outward, are analogous; yet, in most cases, by means of bruit or other characters, an expansile blood-containing tumor can be easily distinguished from a solid neoplasm.

The possible predisposing causative influences of occupation deserve a passing mention. In the case reported at the outset, the patient was a shoemaker, accustomed to press his tools of trade against the sternum. The question might be stated thus: Given, a pure family history, free from taint of malignant disease, the etiology of these tumors in this region may be more readily linked with irritation than is the etiology of cancerous tumors. The cases instanced in this paper were mostly free from an ancestry tainted with malignant disease. The anterior location of these growths in so many cases would also favor the theory of a traumatic etiology.

Sarcomata in the chest, as elsewhere, show a rapidity of development which contrasts with the cancerous type of growth. The general symptoms in cases of intrathoracic sarcoma, such as emaciation or pain, are relative to the size and location of the tumor, and the cachexia of malignant disease is usually well marked.

In the case of the patient recorded under my own observation, the opinion was entertained that we had to do with a malignant growth which would prove a sarcoma. The diagnosis was chiefly based upon the location of the disease in the anterior instead of the posterior mediastinum, upon the age of the patient, upon the rapidity of the progress of the case, which began in April and terminated in the following February, and the exclusion of aneurism chiefly by the absence of the usual signs of a blood-containing tumor.

CASE OF ARTIFICIAL OPENING THROUGH THE ŒSOPHAGUS INTO THE TRACHEA, PRODUCED BY SWALLOWING A DENTAL PLATE.

BY FRANK E. CASTLE, M.D.,
OF WATERBURY, CONN.

MR. F. S., aged thirty-five, unmarried, died of pulmonary consumption April 21, 1883. An autopsy was obtained, having been requested on account of throat symptoms of a peculiar nature, which had existed since swallowing a small, rubber dental plate nearly fifteen years before.

The following history was obtained, partly from the patient during my attendance on the case, and partly from the family.

The father and mother are now living, and in good health. Two aunts on the father's side died of consumption.

A younger brother has had slight hemorrhages at three or four different times, the first five years ago. He is now without cough, and is apparently well. Mr. S.'s health, previous to the age of twenty-one, when he met with this accident, was uniformly good. On the night of December 31, 1868, Mr. S. retired late, and had been sleeping about an hour, when he was awakened by a severe choking cough, and found himself unable to breathe.

He sprang from the bed, and fell unconscious to the floor, but was soon able to rise and hurry down stairs for some water. As soon as he could speak, he related his experience to his mother, and complained of a terrible pain in the chest.

His breathing was difficult, and accompanied by a loud, stridulous noise, as of one with croup. A doctor was summoned, but it was nearly two hours before his arrival.

In the mean time, Mr. S. had vomited freely, and his breathing had become more tranquil. It was considered a case of congestion of the lungs, and treated accordingly. Mr. S. slowly regained his strength, but was constantly harassed with pain and soreness underneath the sternum, and by a

severe cough. On the twelfth day after the attack, he was able to return to his occupation as bookkeeper in a store. On the second day of his illness, he asked for his false teeth, supposing that he had removed the plate from his mouth during the strangling fit, and that it had been laid aside.

It, however, had not been seen, and thinking that it might have been cast out while vomiting, search was made in the snow where the bowl had been emptied but it was not found, although they went so far as to melt the snow with hot water. Even then it was not supposed possible that he could have swallowed it, and these facts were not mentioned to the physician at the time, although later the family were convinced that such an accident had occurred.

After resuming business, his cough persisted, and the soreness beneath the sternum remained; and in the spring his health failed very decidedly. He continued, however, at his employment until the 24th of August, when he went to Minnesota, where he remained eight months. He returned looking much better, but his cough remained the same, and he would frequently choke at the table and reject pieces of food that he had swallowed. At one time, after eating some dried beef, he insisted that a piece had lodged in his throat, and three days later he coughed it up.

In June, 1871, he consulted Dr. Sayre, of New York, who introduced a probang into the stomach, but found no stricture; but a very sore spot was reached, and great pain felt, especially on the withdrawal of the instrument. A treatment of swabbing the throat was instituted by Dr. Sayre, and was carried out for some weeks at home by the family physician. As this seemed of no benefit, and was very painful, it was given up, and for about two years he simply attended to his general health, living in the open air as much as possible, and taking horseback exercise. During these two years, and the two or three following, he had several hemorrhages, in one of which it was estimated that he lost a pint and a half of blood.

About this time, 1872, he engaged again in business, in which he continued until within a week of his death.

When he first came under my observation, he seemed fairly well nourished and of average strength. Besides the symptoms already detailed, he was much troubled with palpitation of the heart, and with the belching of large volumes of air, the latter being much greater after partaking of food or drink. He did not taste the food in the air thrown off, and digestion seemed well performed. He was always a heavy smoker, but cutting down the amount of tobacco used did not much diminish the palpitation.

The heart was free from valvular disease, and the cause of so much belching of wind was not determined.

The difficulty in swallowing already alluded to, demands further consideration, as this symptom bears so directly on what was revealed at the autopsy. Mr. S. found that by bending his head to the left, and projecting his chin forwards and to the right, he had much less difficulty in swallowing and fewer choking attacks. This awkward motion and the liability of expelling his food with great force during these attacks, deterred him from going much into society and he became somewhat despondent, though naturally of a cheerful disposition.

He continued in the state described until early in the winter of 1883, when he commenced to fail in strength and grow pale. His cough also changed in character, and he expectorated abundantly of purulent matter, and it was evident that his lungs were diseased. Another symptom, unexplained before the autopsy, became prominent during the winter.

Mr. S. would occasionally suffer from attacks of pain in the bowels and vomiting, and when failing to obtain relief from domestic remedies, would send for me to inject morphine. I advised change of climate for the winter, but finding it very inconvenient to leave, he remained at home, where he died in April, 1883. His last few weeks were marked by a very rapid failure, and he died with the ordinary symptoms of phthisis

Autopsy (eight hours after death).—Present and assisting, Drs. Holmes and Barber. Body less emaciated than usual after death from phthisis. Pericardium, and heart normal. The left lung free from adhesions: the upper two-fifths tuberculous, with small cavities containing purulent matter. Right lung slightly adherent posteriorly at the apex; the upper third tuberculous. Trachea removed, with a corresponding length of the œsophagus. The two organs were fused together from old inflammatory deposit. On slitting up the œsophagus and trachea, the lesion of special interest was presented.

Two inches from the cricoid an oval opening existed, connecting these two tubes. This opening was situated a little obliquely and slightly to the right of the median line and measured one inch and a quarter in its long diameter. By bending the specimen to one side and at the same time slightly twisting it, the edges of the opening could be made to approximate and close it, thus explaining the position assumed by Mr. S., as mentioned in the previous history.

The stomach was dilated; otherwise normal. The intestines were slit through their entire length, and nothing found abnormal until the ileo-cæcal valve was reached, when quite a thickening was seen surrounding this part. About the middle of the transverse colon, a stenosis of the gut was met with, which would but just admit the forefinger, and this size was maintained throughout the remainder of the intestine, Above this narrowing the canal was somewhat dilated. This condition of the intestines leads to the inference that the plate became lodged there temporarily and then passed on through the bowels.

The attacks of pain already alluded to were probably due to temporary obstruction. Two gall-stones filled nearly the entire gall-bladder, each three-quarters of an inch in diameter; the remaining space was filled by several smaller ones. All of the other organs were healthy.

REMARKS.—In explanation of the large amount of wind which was belched, I offer the following:

That during deglutition, air would pass from the trachea through this opening into the œsophagus and be carried before the food into the stomach, which it simply distended mechanically, for this symptom was most pronounced after meals.

That the plate was swallowed, I think the history abundantly shows; also, that the opening was made by the plate and that it had existed since the illness of 1868, for the symptoms remained practically unchanged from that time until his death.

That the lesion was not the result of syphilis or tubercle is evident, for never has there existed a symptom of the former, and not of the latter until six months of his death.

In searching the literature to which I have access, I can find no case similar to the one here presented.

MEDICAL PROGRESS.

Hydrofluoric Acid and the Fluorides in Aneurism and Cardiac Disease.—Surgeon L. A. Waddell, of Calcutta, who has been making an extended study of the physiological and medicinal action of hydrofluoric acid and the fluorides, says that in aortic aneurism fluorine may be admissible on account of its property of combating vascular fulness; but in endeavoring by its aid to relieve the arterial tension, care must be taken not to induce such an advanced state of anæmia as will aggravate those degenerative changes, to which the aneurismal swelling partly owes its origin. It will also be obvious that the dose must be sufficiently small to avoid the possibility of vomiting. Fluorine is unlikely to assist in the removal of material which is actually effused and organized.

In mitral disease the use of these drugs must be invariably bad, for they weaken the heart, and have none of the tonic and stimulating properties which render digitalis of such value in this affection. In aortic disease the ultimate effect would be to aggravate dangerously the low arterial tension which obtains during the ventricular diastole.—*Indian Med. Gazette*, December, 1883.

Ovariotomy on a Child.—At the meeting of the Gesellschaft für Geburtshülfe und Gynäkologie, in Berlin, on October 26, 1883, Dr. Roemer reported the case of a child, æt. twenty months, upon whom he had performed ovariotomy two months previously.

The child had learned to walk at the age of fifteen months, at which time the parents noticed a peculiarity in its gait. It was taken to the Augusta Hospital, when it was observed that the abdomen was very prominent and the lumbar vertebræ were lordotic, while the dorsal vertebræ and the upper part of the body were bent very far backward. On examination, a fluctuating, movable tumor was felt in the pelvis, which could be recognized as high as the umbilicus. Puncture showed that it contained clear, albuminous serum, and the case was diagnosticated as a mixed cystic tumor, probably of the ovary, though possibly arising from the mesentery. Within two weeks the tumor had grown so much that it extended above the umbilicus and almost to the xiphoid cartilage, and reached on either side to the mammary line. It was again punctured, and about f ℥x of fluid withdrawn. A few days afterwards laparotomy was performed, although the diagnosis of ovarian tumor was not certain. As soon, however, as the abdomen was opened, it was seen that the tumor sprang from the right side of the uterus by a long, thin pedicle. This was ligated and cut off, and the tumor removed entire. The left ovary was found to be perfectly normal. The child made a good recovery.

The pathological examination of the tumor was made by Dr. O. Israel, who found it to be a teratoma.—*Deutsch. med. Wochensch.*, December 26, 1883.

Ligation of Common Carotid for Traumatic Aneurism.—Dr. J. Thad. Johnson, of Atlanta, reports the case of a man who received a penetrating wound from the blade of an ordinary pocket-knife, in the side of the neck, about an inch below the angle of the jaw. Free hemorrhage occurred, but was soon arrested, and then entirely ceased. On the eighth day a small tumor was discovered, which steadily grew. On the twentieth day hemorrhage again occurred, and was again stopped by pressure. The tumor now grew so rapidly that the common carotid was ligated on the twenty-fourth day. Several hours after the operation the patient was discovered to be hemiplegic. He gradually sank, and died thirty-six hours after the operation.—*Southern Medical Record*, January, 1884.

Embolism and Paralysis from Pleural Irrigation.—Escherich has recently reported cases in which embolism and paralysis have resulted from washing out the pleural sac in empyema. He reports a case which occurred in the service of Prof. Gerhardt, of Munich, in which the patient died soon after an apoplectiform attack. The autopsy showed an abscess situated under the dura mater on the left side, with other smaller abscesses in the left hemisphere. Leichtenstein has published a similar case; and Dusch has reported one in which an embolus of the pulmonary artery was caused by washing out the pleura, as was shown by the autopsy.

Nervous accidents are also seen to occur during the operation, their pathogenesis being still a matter of some doubt. Paralysis of the arms and other parts of the body has also been known to be caused by this operation, and Lépine has seen reflex paralysis in cases of this nature, having its origin in the intercostal nerves.—*Gaz. Méd. de Paris*, Jan. 19, 1884.

Excessive Vomiting of Pregnancy.—In a recent paper on this subject Dr. Sutugin draws the following conclusions:

1. Excessive vomiting is one of the uncommon affections of pregnant women.

2. The affection appears after the second, and up to the last months of pregnancy; but it is much more frequent during the first half of the period of pregnancy.

3. The affection is more frequent amongst the richer classes. Race has no influence in its production.

4. It is more frequent in multiparæ.

5. The symptoms of the affection are very analogous to those of inanition, which explains the decreased urinary secretion, and the presence of albumen and cylinders in the urine.

6. In order to solve the question of the frequency of the appearance of albumen and casts in the second period, further observations are necessary.

7. Death takes place either by exhaustion or by in-

tercurrent puerperal disease, or from complicating diseases which have no direct relation with pregnancy.

8. The nature of the affection is still unknown.

9. The treatment should correspond to the different periods of the affection. If therapeutic means fail in the second period, premature delivery should be resorted to.—*Archives de Tocologie*, February, 1884.

The Treatment of Rheumatic Facial Paralysis.—At the close of a paper on this subject, read before the Berliner Medicinische Gesellschaft, on January 9th, Dr. Moritz Meyer drew the following conclusions:

In facial paralyses of a severe type, leeches, cataplasms, etc. are to be recommended—to hasten the cure on the one hand, and, on the other hand, to limit the number of degenerating nerve-fibres.

2. After the use of leeches, cataplasms, etc., direct manipulation over the nerves gives better results than have hitherto been obtained by electricity.

3. In chronic cases, the electric stimulus of strong faradic currents over the nerves should be tried, in order to stimulate the normal nerve-fibres, and increase the mobility and nutrition of the paralyzed muscles.—*Deutsche med. Wochensch.*, Jan. 17, 1884.

Inhalations of Oxygen in the Anorexia and Vomiting of Pregnancy.—Dr. A. Mayer reports four personal cases, and one of Dr. Maunoir, which show the influence of oxygen in combating the anorexia and vomiting of pregnancy. In these cases the symptoms did not present the same degree of intensity, but all showed the surprisingly rapid effect of the oxygen treatment. After the first inhalation of from five to ten quarts of oxygen the amelioration was undoubted, and a few inhalations were sufficient to give excellent results. In very severe cases reported by Pinard, the oxygen treatment succeeded after other therapeutic agents had been tried in vain. This method is perfectly harmless to the fœtus.—*Journ. de Méd. de Paris*, February 2, 1884.

Experimental Proof of Hydrophobia.—A boy, aged seven years, died with a curious collection of symptoms, which were similar to those of hydrophobia. Prof. Pasteur, to establish the diagnosis, inoculated two dogs and two rabbits with portions of the cerebral substance and the medulla. All four of the animals died with symptoms characteristic of the disease.—*Gaz. Méd. di Torino*, February 15, 1884.

Moist Spreading Gangrene of Foot and Leg in an Old Man; High Amputation.—Mr. Rivington, of the London Hospital, reports the case of a man, æt. 63 years, who suffered from moist spreading gangrene, caused by a slight accident. The gangrene extended to the ankle-joint, and the skin of the leg presented an inflammatory appearance to within a couple of inches of the knee-joint, and the limb was œdematous. The glands in the groin were enlarged. On the next day Mr. Rivington amputated the leg immediately above the knee. The arteries were atheromatous. On the following day the edge of the anterior flap was found to be gangrenous, with a suspicious dusky redness extending upwards. Two days later, the gangrene of the anterior flap had spread, but on the following day the stump looked better, and a line of demarcation had formed. Four days later the carbolic dressings were abandoned; the stump was thoroughly irrigated, powdered iodoform was dusted over it, strapping used to approximate the flaps, and cotton-wool and bandage applied. The patient slept and ate well. He wandered a little on one or two occasions. From this time the wound granulated healthily; the bone, which had protruded after retraction of the flaps, became gradually less prominent as the edges of the flaps approached each other during the healing process. Mr. Rivington believes that amputation saved the patient, although, of course, it is not possible to assert this positively. Neither can any very definite rule be laid down as to the choice of amputation or leaving the case to nature in senile gangrene. In some cases where the patient's arteries generally are diseased, when pressure induces gangrene of the soft parts over prominent points of bone, and when the patient appears broken down and worn out, amputation would speedily extinguish life; but on the other hand, he is persuaded that some of the many cases which have died when left to nature would have had their lives prolonged by operation.

As regards the seat of amputation for gangrene of the foot and lower part of the leg, the lower third of the thigh appears to him to be the safest and best place, as in cases which follow plugging of the femoral artery the gangrene rarely extends beyond the lower part of the thigh. Here the vitality of the part is greater, the healing powers more active, and there is far less liability to a return of the disease than there would be below the knee. In his own experience amputation in the lower third of the thigh is a very successful procedure, especially with antiseptic precautions. Whether high amputation should be resorted to or not in other forms of gangrene is not so clear. In traumatic cases and in septic cases he has generally amputated immediately above, but clear of, the disease, and he followed this practice in a case of double amputation for gangrene from frost-bite with a successful issue, and without the recurrence of gangrene or sloughing of the flaps.—*Lancet*, February 16, 1884.

Porro Operations.—In a letter to the *British Medical Journal*, of February 16, 1884, Dr. Clement Godson states that Dr. H. Fehling, of Stuttgart, performed his fifth Porro operation, on January 26th, in a case of rickety pelvis. Both mother and child are well. His five operations have given four recoveries, the same result as obtained by Prof. Porro. He also states that Dr. Savage performed the operation during the sixth month of pregnancy, in Sept. 1883, the patient recovering.

Extirpation of Goitre by Means of the Elastic Ligature.—Dr. G. Usiglio reports the case of a patient, æt. 56, who had enlargement of the thyroid body, due to hyperplasia of the left lobe, in which the enlargement was removed by means of the elastic ligature. The part came away in five days, and the patient recovered easily.

Two months previously, March, 1833, Dr. G. B. Masta had successfully employed the same means for the removal of a pedunculated tumor. De Vecchi and Castelleone have also reported cases.

An incision is made in the skin, in which the ligature is placed, the wound being disinfected and the ligature tightened daily.—*Gazz. degli Ospitali*, January 16, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, MARCH 15, 1884.

ENTERECTOMY AND ENTERORRHAPHY IN GANGRENOUS HERNIA.

THE management of the gangrenous intestine in cases of strangulated hernia is, in view of the evil consequences which are liable to follow the condition of the bowel, a question that involves more than ordinary judgment and demands serious consideration. The usual practice, after having relieved the stricture, is to open the tube and attempt the establishment of an artificial anus. That efforts in this direction have for many years been regarded with disfavor is shown by the fact that Ramdohr, in 1727, excised two feet of the mortified bowel, stitched the ends together, and saved his patient. Up to 1846, the operation was repeated by De Vermale, Duverger, Schmid, Nayler, Boyer, Lavielle, Dieffenbach, Luzenberg, and twice by Astley Cooper, the entire 11 cases having resulted in 7 complete cures, 1 recovery with an artificial anus, and 3 deaths.

The procedure appears to have been lost sight of from 1846 to 1873, when it was revived by Lücke, and it has been practised during the past ten years at least sixty-seven times. It consists, in a few words, of relieving the stricture, drawing down and resecting the dead gut along with its attached mesentery, reëstablishing the continuity of the canal by appropriate sutures, and returning the parts into the abdominal cavity.

In our account of the results of the operation and some points concerning its proper performance since its revival, we have to express our indebtedness more especially to several papers which have appeared during the past year, of which the most noteworthy are those of REICHEL, of Breslau, BOUILLY, of Paris, and ILL, of Newark, which may be found, respectively, in the *Deutsche Zeitschrift für Chirurgie*, Bd. xix. Hefte 2 and 3, the *Revue de Chirurgie*, No. 5, and the *Medical Record*, Vol. 24, No. 12.

Circular resection and suture of the intestine in strangulated gangrenous hernia has been done by Fischer and Obalinski, each in 4 cases, by Billroth, Kocher, and Kuester, each in 3 cases, by Bardeleben, Bouilly, Bryk, Czerny, Dittel, Hagedorn, Ill, and Wittergren, each in 2 cases, and by Aman, Bardenheuer, Borel and Scherer, Feld, Fuller, Gaittai, Gussenbauer, Hertaux, Heusner, Jaffé, Julliard, Korzeniowski, Kosinski, Krönlein, Langenbeck, Ludvik, Lücke, Marcy, Molodenkow, Nicoladoni, Porter, Prati, Riedel, Rochelt, Roggenbau, Roser, Rydygier, Schede, Taendler, Viertel, Von Wahl, Weinlechner, Weiss, and Wolfler, respectively, in 1 case. Of the 67, 21 were complete cures, 2 recovered with an artificial anus, and 44, or 65.67 per cent., died.

As might naturally be expected, peritonitis was the cause of the fatal issue in the majority of cases. In two it was due to alcoholic delirium, so that, even if these cases be excluded, the mortality is twice as great as that following resection and suturing of the gut for artificial anus, as was pointed out in the editorial columns of THE MEDICAL NEWS for February 2d. This difference may, however, be readily accounted for when the condition of the intestine in the two lesions is considered. In gangrenous hernia the divided ends of the gut are very liable to be œdematous, ecchymosed, and inflamed, through which they are rendered soft and lacerable. That the circulation of the gut at the point of suture is extensively damaged is shown, first, by the cases of Kocher and Taendler, in which the upper end became gangrenous above the point of operation, respectively, for four and six inches; secondly, by three examples of laceration during the necessary manipulations; and, thirdly, by three instances of giving way of the sutures. In resection for artificial anus, on the other hand, sound intestine is divided and sutured, and these exciting causes of peritonitis, except it may be loosening of the stitches, are gotten rid of.

In performing the operation the following points should command the most careful attention:

1. To prevent effusion, the lumen of the gut must be temporarily occluded. This may be accomplished with a provisional catgut or silken ligature, but this method is open to the objection of throwing the intestine into folds which interfere with the proper insertion of the sutures. The occlusion may be effected with a clamp or forceps, or, still better,

with the fingers of assistants, as advised by Billroth, Fischer, Gussenbauer, Czerny, and Ill.

2. If gangrenous, a triangular portion of the mesentery should be removed, and the edges united by suture after the vessels are secured; if sound, it may be ligated in mass. In either event, the mesentery must not be separated from the bowel beyond the points of severance of the latter, lest gangrene of the edges of the wound ensue. Rydygier advises that the mesentery receive attention after the intestine has been resected, but in this he has no followers. The gut should be divided at a right angle to its axis, unless one end is smaller than the other, when the cut should be made at an acute angle.

3. The most important step of the operation is the insertion of the sutures, the material for which, in the present state of our knowledge, should be pure silk soaked in a proper solution of corrosive sublimate. The safest and most efficient mode of uniting the severed ends of the gut is with what is known as the Czerny-Lembert suture. This consists of an inner row of stitches, which are inserted at a distance of one-eighth of an inch from one another, and which include all the coats of the bowel, and an outer row, not so close together, each of which includes the serous covering only, and constitutes the classical suture of Lembert. If it should happen that the mucous membrane protrudes too much, as it may through the retraction of the muscular tunic, it should not be cut off on a level with the latter, as advised by Ill and Rydygier, but the inner row of stitches should be applied in such a way as to exclude it. Finally, the accurate approximation of the edges of the wound will be greatly facilitated if the first suture be inserted on the mesenteric side of the intestine, and the second at a point directly opposite.

As we have already seen, the damaged condition of the gut in the immediate vicinity of the gangrenous portion is the chief cause of failure after the operation. Hence, to insure better success in the future, the intestine should be resected only through a sound and undistended portion, beyond the seat of infarctions and effusions, since the sutures still further interfere with the vascular supply, and render partial or total gangrene of the edges of the wound imminent. It is for this reason that we consider the course pursued by Riedel, as described in the *Deutsche medicinische Wochenschrift*, No. 45, 1883, as being worthy of imitation. The gangrenous portion of the intestine having been withdrawn from the sac, and attached to the thigh by a few stitches, is drained by a large tube passed into the upper portion of the bowel. At the end of twenty-four hours, the parts in the interval having been kept moistened by naphthaline, or other antiseptic agent, the normal condition of the gut will have been restored, as indicated by the disappearance of the local signs of inflammation, and the return of its firmness, when the operation may be proceeded with. Whether this course be pursued or not, care must be taken to cut through sound tissues, even at the expense of removing a larger amount of the tube, which really appears to be a matter of very little moment, as the cases do as well after resection of eight or ten inches as after the excision of two or three inches.

The question naturally arises, Does circular resection and suturing of the gut in gangrenous hernia present any advantages over attempting the formation of an artificial anus? In the present state of our knowledge, an intelligent answer can scarcely be made, because we know so little of the mortality of the latter conservative course. Ill has collected 29 cases, of which 25, or 86 per cent., died; and Benno-Schmidt, of Leipzic, in a paper read at the last Congress of the Association of German Surgeons, and published in the *Centralblatt für Chirurgie*, No. 23, 1883, places the mortality at 80 per cent. Hence, although Billroth, Dittel, Von Bergmann, Julliard, and Reichel favor the formation of an artificial anus, we think the surgeon will be wise who resorts to the operation which we have now considered, provided he imitates the example of Riedel, and also takes care to select sound portions of the gut for resection and suturing. If successful, the recovery is absolute; if it fails, and the patient survives with an artificial anus, or fecal fistule, his condition is not worse than if the operation had not been practised.

THOMSEN'S DISEASE.

Under the term *ataxia muscularis*, Dr. Thomsen described a new nervous affection, which consists in the occurrence of muscular spasm at the beginning of a voluntary movement. Prof. Westphal, recognizing the originality of Thomsen's observation, first coupled the discoverer's name with the new affection. Cases have been published by Seeligmüller, Bernhardt, Strümpell, Weichmann, and Mobius, in Germany, and by Ballet and Marie, in France. The phenomena observed in the various cases have been very uniform.

The affection consists essentially in muscular spasm, which comes on as any voluntary movement is attempted, but which disappears on a repetition of the movement. The affection is hereditary, and, as it manifests itself in infancy, is doubtless congenital. In most of the cases, there is a hypertrophic enlargement of the muscles. The cramps are notably increased by fatigue, and when, after a period of repose, the patient again attempts movements.

All the muscles of the body, including those of the eyes and tongue, may be affected. The electric

reaction and the cutaneous and muscular reflexes remain normal, and sensibility is unimpaired. The condition of the muscles is that of exaggerated reaction to the motor impulses or excitations.

The increase in the volume of the muscular masses, the hereditary character of the affection, and the marked predominance of the cases in males, ally this affection with pseudo-hypertrophic paralysis.

UNDERBIDDING FOR STUDENTS.

The *exposé* by Dr. David W. Yandell, in the February issue of *The American Practitioner*, of the recent proceedings of the Louisville Medical College, is, to say the least, humiliating to those who had commenced to hope that the profession in America was becoming more elevated in tone as it was growing in intelligence. Judging from the practices of some of the professors of this "foremost school in the country," before and after their connection with it, it would seem that association with some medical colleges, at least, is as demoralizing as horse-trading. We have ourselves seen one of the letters offering to take students on the so-called "beneficiary" reduction-rate basis, which have been published by Dr. Yandell. It was sent to a student of medicine, and offered largely reduced rates, and urged the claims of the Louisville Medical College and of Louisville, "the medical centre of the South and West, the healthiest large city in America; beyond the reach of yellow fever," etc.

We sincerely trust that some efficient remedy for such degrading and disgraceful practices, "hurtful to the best interests of medical teaching, medical men, and medical students," shall be speedily discovered. Till then, the best that can be done is to expose such practices to public gaze and public scorn, and the thanks of the profession are due Dr. Yandell for the fearless performance of this unpleasant duty.

In this connection it seems pertinent to reflect on the results of gratuitous instruction at colleges in general, and especially at medical colleges. The general effect of indiscriminate disbursement of free scholarships is baneful in inviting to the study of medicine those who are utterly unfit for it, by reason of their want of the requisite preliminary education. Such opportunities should always be limited, and they should be awarded only upon competitive examination, which does not exclude the deserving and energetic, while it eliminates a large number of utterly unsuitable applicants.

We, therefore, note with regret a circular issued by the University of Minnesota, in which it is stated that tuition is absolutely free, and that the Medical Faculty constitutes an examining and licensing body. At present no instruction is offered, but the degrees in medicine of the University are conferred upon all persons who pass the examination.

A propos of the above, and showing that the profession itself is not responsible for these degrading practices, and the resulting low standard of medical education, we take pleasure in calling attention to a circular issued by the Medical Society of Trumbull County, Ohio, containing a schedule of subjects for a preliminary examination, to be hereafter exacted of those who propose to study medicine under the tuition of members of the Society.

A schedule adopted early in 1882 has been amended to secure uniformity with that adopted by the Medical Society of the State of Pennsylvania in June, 1883. The Society recommends that the period of study required be five years, and that its members shall require their students to attend only such medical colleges as either require an examination for admission similar to the above or make the full three years' graded course obligatory.

Such influences as these cannot be without their effect, and it is to be hoped that the leaven thus introduced will so rapidly extend itself as to more than counteract the opposite influence.

SOME RECENT SURGERY OF THE STOMACH.

Since the appearance, in the editorial columns of The Medical News for November 24, 1883, of a critical inquiry into the merits of resection of the pylorus, several new cases have been recorded, which sustain the view expressed at that time—that it should not be performed, at any rate, for carcinoma.

In the *Correspondenzenblatt für Schweizer Aerzte*, for Nov. 1883, may be found three cases of operation for carcinoma by Kocher, of which two died within twenty-four hours, and one was living twenty-four days subsequently. Another fatal result in four hours is reported by Maurer, in the *Archiv für Klinische Chirurgie*, Bd. xxx. Heft 1, 1884, and he informs us that the case of Czerny, which was living at the expiration of ten months, when we referred to it, expired, eight months subsequently, with local recurrence.

Maurer also gives the details of a case of ulcer of the stomach, in which Czerny resorted to a new procedure, which possesses manifest advantages over pylorectomy. Instead of making an ordinary resection, and attaching the duodenum to the stomach, he opened the latter transversely to its long axis, by an incision carried through the lesser curvature, scraped away the greater portion of the ulcerated surface, and covered in the defect with twenty-six stitches inserted through the mucous membrane, and, finally, removed the remainder of the ulcer by ex-

cision of an elliptical portion of the entire thickness of the stomach, which was closed in the usual way. The man made a rapid recovery, and had gained twenty pounds in weight at the expiration of three months.

STATE APPROPRIATION TO MEDICAL SCHOOLS.

THE Bill brought before the General Assembly of Virginia, providing for a State Board of Examiners, and which has now become a law, was noticed in a late issue of THE MEDICAL NEWS.

The Assembly has now before it a bill appropriating $7500, annually, to the Medical College of Virginia, situated in Richmond, and providing,

"That there shall be admitted to the Medical College of Virginia, while this amount is paid, free from all charge for tuition, . . . as many students, who are citizens of Virginia, as there are members of the General Assembly, each member of which is hereby empowered to nominate, in each year, from his county or district, a student to the faculty of the said college, who may prescribe the academic qualifications of the nominee."

As regards the bill it may be said, in the first place, that the clause just quoted is as ambiguous as it is bad. The "who," in "who may prescribe," may refer either to the faculty or to the nominating member. In the latter case, it is especially bad, since the member might send a student whose educational advantages had been *nil*, and compel the faculty to receive him.

Again, the bill is bad, because a Legislature has no right to appropriate public money to give a citizen a professional education. If the medical student receives State aid, why not the law student, and those entering other professions.

Public policy has emphatically declared that "public education can only be justified on the ground that the citizen, by being taught the elements of education, is thereby better fitted to discharge his duties to society as a citizen in those functions which are common to all citizens. This reason utterly fails to apply to professions and professional education. They are *special* and *individual*, and, therefore, outside of the reason which vindicates public school instruction for the masses." No one, by reason of his influence with a politician, has a right to be furnished with a business at the public expense. It would be misappropriation of public money, and therefore unjust. Moreover, such an appropriation of public money to one institution is unjust and injurious to other institutions in the State, and on this ground should not be permitted.

THE EXCLUSION OF AMERICAN PORK FROM THE GERMAN EMPIRE.

WE call especial attention to the important facts contained in the report to the Surgeon-General made by Assistant Surgeon Pope, which appears in another column. The entire exemption from trichinosis of the American soldiers in the United States Army, though the American hog is a conspicuous part of their diet, shows very clearly that, to prevent the disease in Germany, lessons in cooking are more needed than exclusion of American pork.

If Charles Lamb is to be believed, the Chinese for seventy thousand ages ate their meat raw, clawing it or biting it from the living animal, and then only accidentally learned how delicious roast pig was. If Germans will eat their pork half-cooked they are little in advance of this ancient practice of the people of Confucius, and need to be taught, by the conflagration of a few pigsties, as the Chinese were, or by the burning of their butcher shops, the excellence of properly cooked pork. The protection that this cooking gives the eater will need no other enforcement.

In striking and favorable contrast with the action of the German authorities is the conduct of the French Government. The latter referred the question of the introduction into France of American pork to the Academy of Medicine of Paris; the Academy appointed a Commission to consider the subject, and on the 22d of last January this Commission made its report, and its conclusion is, that as no case of trichinosis has been ascertained to have occurred in France or in England from the use of salted American pork, its importation can be authorized in France.

WE invite the attention of our readers to an excellent paper "On the Artificial Culture of Disease Germs, and what it Teaches," read by DR. D. E. SALMON, of the Agricultural Department, Washington, before the Brooklyn Pathological Society, and published in its *Proceedings* for January, 1884. Dr. Salmon presents fully and clearly the difficulties in the way of such culture, the methods by which they are overcome, and the import of the results.

Dr. Salmon has also published a short paper in *Science* for February 8, 1884, in which he sustains very conclusively the claims of Dr. Klein, of London, as the discoverer, as far back as 1876, of the micrococcus of the swine plague, or pig cholera, although he failed to recognize its importance, and even afterwards pointed out a bacillus as the cause of the cholera, which seems now to be generally acknowledged to have been an error. Dr. Salmon himself was the first to demonstrate by satisfactory methods that this micrococcus exists in the blood during life; that it can be cultivated in flasks; and that the sixth successive cultivation, made with considerable quantities of liquid, and which contained no other organism than micrococcus, still produced the disease. He disproves the correctness

of the statement by Pasteur, in a communication to the Paris Academy, November 26, 1883, that Prof. Detmers, of Chicago, was the first to discover the microbe.

We note with pleasure that our contemporary, *The New York Medical Journal*, shows signs of becoming disgusted with the working of the New Code. The dissatisfaction expressed by the Homœopathic State Society in not being given equal representation in the proposed State Examining Board leads it, in its last issue, significantly to declare that, "it ought now to be plain that there is nothing to be gained by attempts to propitiate the sects."

SPECIAL ARTICLE.

TRICHINOSIS IN THE ARMY.

THE following report of ASSISTANT SURGEON POPE of the United States Army, to the Surgeon-General, is of considerable interest in connection with the present animated discussion growing out of the exclusion of American pork from the German Empire:

"The appearance of frequent epidemics of *trichiniasis*, not only among the civil population of that nation, but also among its troops, who might be supposed to be guarded with particular care from all infected food supplies, is well established.

"From the published returns of the Royal Prussian Army for seven years, from 1874 to 1881, I have been able to compile the accompanying table, which exhibits 445 cases of *trichiniasis*, with 15 deaths, in an aggregate of 1,408,273 cases of disease from all causes, and 8312 deaths; the average strength of the forces for that period being 326,608, officers and men.

Royal Prussian (German) Army.

Year.	Mean Strength	All Causes. Diseases.	All Causes. Deaths.	Trichiniasis. Cases.	Trichiniasis. Deaths.	Remarks.
1874-75	311,609	223,033	1285	103	1	
1875-76	327,254	220,670	1462	65	2	
1876-77	339,046	194,924	1219	28		
1877-78	327,271	198,853	1113	149	12	107 cases reported from the VIII. Army Corps alone.
1878-79	327,298	187,243	1093	17		
1879-80	330,430	190,444	1067	49	...	47 in the Guard Corps in Berlin.
1880-81	331,747	193,306	1073	43	...	17 cases in the II. Army Corps.
Total.	2,286,255	1,408,473	8312	445	15	
Yearly Average.	326,608	201,210	1187	64	2	

"In marked contrast to this condition of affairs, although trichinous poisoning has from time to time been reported among the civil population of the United States, American troops show singular exemption. A very careful examination has been made of the returns received at the office of the Surgeon-General for a period of eighteen years subsequent to June 30, 1866. These returns exhibit the fact that there have been treated 910,367 cases of disease from all causes, with 7191 deaths, in an average force of 29,171 officers and enlisted men, without a single case of *trichiniasis* appearing.

"A further examination of disease and mortality returns for the five years of war from 1861 to 1866 was made, and a grand aggregate of 6,029,564 cases of disease, with 156,885 deaths, was shown in an average force of 532,198 officers and men, without a case of *trichiniasis*.

"Prior to the year 1865, it is not impossible that cases of *trichiniasis* may have occurred among American troops and escaped attention, but since that date this singular disease has taken so prominent a place in medical thought and medical literature, that it is difficult to believe that any number could have occurred without detection by officers of the Medical Department of the United States Army.

"In partial explanation of this remarkable immunity, it may here be stated that the use of fresh pork in any shape is not common among American troops, since by reason of their enforced isolation, either at frontier stations or in garrisons remote from village or city life, they are precluded from over-indulgence in that particular.

"At some favored posts, the carefully tended company-pig is slaughtered for Thanksgiving or Christmas dinner; but it is always thoroughly cooked, and lasts but a short time.

"While, as stated, fresh pork is rarely used, the American hog, in the form of bacon and ham, has always been an important article of diet; three-sevenths of the meat-ration, which by law consists of twenty ounces of fresh beef or twelve ounces of pork per diem, being the usual allowance of the soldier at permanent military stations. To troops in the field, or on the march, the whole meat-ration is issued in bacon and in bulk. As used, the pork is usually thoroughly cooked; but emergencies often arise where it can be eaten only in the raw state, and in connection with hard bread, which is another component of the field ration; but, whether cooked or raw, were trichinous poisoning to occur, it must appear as an epidemic that would inevitably attract attention, and cause immediate report; and its non-existence upon the health returns is believed to be good evidence of its non-existence in the Army.

"Prussian troops, on the contrary, are stationed in thickly populated communities, are often quartered upon the inhabitants, and live in the utmost intimacy with them. At Berlin, where the Guard Corps is stationed, forty-four cases of *trichiniasis* were reported in 1879, all of them arising from meat furnished by one butcher. At Spandau, during the same year. *Schlackwurst* (a sausage composed of fresh pork, mixed with chopped veal, and

parboiled) was responsible for the epidemic among the troops.

"In whatever place stationed, the German soldier has at all times free access to innumerable cheap eating houses, where half-cooked or parboiled fresh pork, sausage, pig's-blood puddings, rye loaves, and thin beer, form staple articles of diet; and here it is that the German, whether civilian or soldier, poisons himself wholesale with trichinous pork.

"Could it be reasonably established, that the American hog was even to a moderate degree, the vehicle for transmission of *trichinæ spiralis* to German stomachs, an anomalous and contrary condition of affairs would surely be shown by the foregoing statistics; namely, that the German soldier at home, though carefully guarded by the rigor of 1800 Royal Sanitary Inspectors stationed through the Empire, to protect him from the dreadful scourge, contracts *trichiniasis* from alleged American pork, while his German brother abroad serving in the American Army, and fed a liberal daily allowance of genuine American pork, escapes without a pang.

"The weight of evidence is certainly against the supposition that the American hog is responsible for the existence of the *trichinæ spiralis* in Germany, and it may safely be predicted that even if he be successfully excluded from that country by vigorous prohibitions, *trichiniasis*—a disease unknown in the American Army, of rare occurrence on American soil, almost unknown in England (in fact, not mentioned as a cause of death upon the returns of the Registrar-General)—will continue to exist in the future, as in the past, so long as German hogs, whether bearing American labels or not, are eaten in German ways."

REVIEWS.

THE DISSECTOR'S MANUAL. By W. BRUCE CLARKE, M.A., M.B., etc., and CHARLES BARRETT LOCKWOOD, F.R.C.S., etc. 16mo. pp. viii. 390. Philadelphia: Henry C. Lea's Son & Co.

THIS is another excellent member of the set of manuals for students, of which we have already noticed several volumes. The authors are men of practical experience in teaching anatomy, and have the ability—which does not always accompany this—of communicating to others in pleasant and agreeable shape the lessons they themselves have learned. As a consequence, the suggestions of the book before us are of a kind which may be well commended to the student of anatomy as a help to him in his dissections. The large number of pages in the book make room for a good deal of material which is generally, or used to be—for there is already a great improvement in this respect—left to works specifically devoted to what is called regional or surgical anatomy. This is a part of anatomical study which cannot be begun too soon. It teaches anatomy and surgery at once, and the learning of each helps to fix the other in the memory.

The illustrations of this book are very good. If we have any fault to find, it is with the glossary, which is in some points ludicrously elementary and in others obscure. There are also some awkward expressions to be found here and there. But, with the exception of these minor defects, we find the book singularly free from anything to criticise adversely. On the other hand, it abounds in practical and suggestive ideas, and can be recommended not only to the student, but also to the practitioner. Its compact form and succinct style make it just the thing for busy men.

LESSONS ON THE HUMAN BODY; AN ELEMENTARY TREATISE UPON PHYSIOLOGY, HYGIENE, AND THE EFFECTS OF STIMULANTS AND NARCOTICS ON THE HUMAN SYSTEM. By ORESTES M. BRAND, Principal of Grammar and Primary School No. 4, Paterson, N. J. 8vo. pp. xii. 227. Boston and New York: Leach, Shewell & Sanborn.

THE publishers of this book, with commendable prudence, have allowed Mr. Brand to copyright the book in his own name. We say with commendable prudence, for if the book be sold on its merits, and not foisted upon ignorant or careless school committees by interested partisans, it will fall flat.

It would seem that Mr. Brand is not a doctor, and hence submitted the latter part of his MS. (on alcohol and tobacco) to Dr. Albert Day, of the Washingtonian Home, Boston. Would that Dr. Day had seen also the remainder of the MS.! *Ne sutor ultra crepidam.*

This part on alcohol is the best of the book, but it is poor and weak and not seldom incorrect. Thus (p. 181) some of the blood corpuscles under the influence of alcohol, it is stated, "throw out matter, which floats about in the fluid portion of the blood;" and the "loss of strength in the corpuscles [due to alcohol] is indicated by black specks of fatty matter, which in all cases of disorder in the blood are found in great numbers." Moreover (p. 184), the alcohol so hardens the brain, that the doctors often can dissect it without further hardening; and when sudden death occurs from drinking, it is "by the rapid massing of alcohol in the brain."

But in the earlier part of the work are found the worst errors. It would be no great matter if Mr. Brand, Principal of a grammar school, did not know exactly what cataract is, but when he publishes a text-book, albeit for elementary schools, and announces cataract as "a thick, milky matter spread over the cornea," and that the remedy is to "cut away a portion of the cornea,"(!) it then becomes a matter of public importance. Even in so simple a matter as the position of the eye, he seems to have a happy faculty of blundering. "The eye is situated . . . in hollows of the bones." How many hollows forsooth?

We can only gather up here and there a few of the many blunders as specimens. The inferior dental nerve "finally supplies the muscles of expression." Fig. 23 represents "the cranial nerves" as three branches of one trunk, which arises in the cerebellum. In fact, except one or two, most of the figures are execrable, both anatomically and artistically. The cornua of the thyroid cartilage are represented as "other cartilages" of the larynx, and the "Adam's apple" is represented in the middle of the lateral aspect of the thyroid cartilage by spots which can only be intended for the core and seeds

of that fatal fruit. Fig. 1 represents the lumbar spine as convex posteriorly, and the splenic curvature of the colon is marked (Fig. 19) as the "greater curvature of the stomach." On page twelve, we learn that the pelvis has four bones, and on page eighteen that it has but three. The madder experiment on the growth of bones, is most confusedly told, and "proves," so our sapient author says, that the bones "grow from the surface toward the center."

One would suppose that Mr. Brand, even if he did not know sufficient anatomy and physiology for a "grammar and primary school," should know a bit of Latin. But among his etymological brackets, we note *capilla* a hair, *tri* three, *motum* to move, *fermentum* to boil, *femoris* the thigh, *choroides* fleecy, and several more such.

But we must leave this little book and we do so with pleasure, in quoting one sentence (p. 101) we can all say amen to. "Indeed"—observe the delicious naïveté of the author's diction!—"Indeed, it may be *safely asserted* that carbonic acid gas *when undiluted* CANNOT BE BREATHED!" Quite so! Quite so!

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 26, 1884.

THE PRESIDENT, R. F. WEIR, M.D., IN THE CHAIR.

DR. A. G. GERSTER presented a patient who showed the result of three plastic operations for

RODENT ULCER.

A woman thirty-four years of age, married, presented herself to him about one year ago with a flat epithelioma, or what the older writers called rodent ulcer, on the left cheek. The disfigurement was very great. The size of the deeply depressed ulcer was about that of a silver half dollar, the main body of which occupied the region of the masseter muscle, and there was pseudo-ankylosis of the lower jaw due to scirrhous contraction of the new growth. Dr. Gerster proposed to remove the ulcer, and made a good prognosis so far as relapse of the disease was concerned, basing it principally upon the fact that none of the adjacent glands were affected. The patient, however, did not consent to be operated upon at that time. She returned in September last, with the ulcer twice as large as it was when he first saw her. Perforation into the oral cavity had taken place in the middle of the ulcer, and there was a continuous oozing of saliva from the opening. She then consented to submit to the operation, and on the 27th of September, 1883, he removed the entire cheek, together with a portion of the horizontal part and the angle of the lower jaw on the left side, commencing at about two inches from the median line, and also a small portion of the alveolar process of the superior maxilla. When the operation was finished the tongue could be seen for its entire length, and also the jaw which remained. He did not make an effort to close the wide opening by a plastic operation at that time, but waited until cicatricial contraction should diminish the size of this enormous defect to such an extent that a plastic operation could be performed, the object of which would be twofold; first, to form a new cheek, and second to prevent the recurrence of ankylosis of the lower jaw, which would have necessarily followed, in consequence of cicatricial contraction, had no plastic material been interposed between the two edges of the wound.

In order to accomplish this he was obliged to follow a plan which was not original with himself. The only case in which the method had been adopted, as far as he could ascertain, was one reported by Gussenbauer, in Langenbeck's *Archiv*, who performed a similar operation on both cheeks, the operation being rendered necessary by noma. Dr. Gerster followed the same plan substantially in his case. The first indication, then, was to give the oral cavity a lining. On the 25th of October, therefore, he raised a tongue-like flap from the temporal region an inch and three-quarters wide and three inches long. It was turned into the defect so as to present the epidermal surface toward the oral cavity. None of the mucous lining of the cheek could be saved at the first operation. There were, therefore, no soft parts remaining to which this flap could be attached, and consequently he drilled three holes in the alveolar process of the lower jaw and four in the alveolar process of the upper jaw, and to these the flap was attached by silver sutures. Primary union ensued, and a little more than four weeks later he proceeded to cover up the granulating surface corresponding to the lining of the oral cavity. To do this he raised a flap from the neck and turned it up into the space, and fastened it with a number of silver wire sutures. This flap at its apex necrosed for a short distance, because of the inequalities of the surface and lack of precise adjustment throughout its entire extent.

Dr. Gerster presented this patient because the case was not yet completed, as there is still one deformity to be corrected, namely, the angle of the mouth is drawn to the left side, and when that correction shall have been made he will present the patient again to the Society. At present she is able to open the mouth widely, and her ability to do so is improving from day to day.

OSTEOTOMY FOR GENU VALGUM—MCEWEN'S METHOD.

DR. C. T. POORE presented a patient, a girl three and a half years old, upon whom he had performed osteotomy on the right leg. The operation was performed three or four months ago, and was resorted to because he was unable to correct the deformity by means of mechanical appliances, the external lateral ligament becoming relaxed. It was the youngest patient upon whom he had ever performed the operation, and the correction was perfect.

DR. F. LANGE then made some

REMARKS ON EXCISION OF THE ANKLE-JOINT WITH SPECIAL REFERENCE TO TECHNIQUE AND AFTER-TREATMENT.

I am going to present six patients, for whom I have excised the ankle-joint more or less extensively within the last two years. In five of these cases the operation was done for scrofulous disease. The patients were, at the time of the operation, from one and a half to nine years old. In one case a gunshot-injury gave the indication. The patient is eighteen years old. I shall

not discuss the question, how far excision of an ankle-joint for scrofulous disease is indicated. Certainly a great difference of opinion exists regarding this point. A number of surgeons, especially in England and America, are in favor of expectant treatment. During six years of living in New York, I have not seen a single excision of the ankle-joint except one, which, strictly taken, was no excision, nor have I heard of one, and I am perfectly aware that in children a great deal can be achieved by mere expectant treatment. On the other hand, I hope to prove by my cases, that very good results can be reached by excision; that the course of the disease in some cases is undoubtedly shortened by years; and in some that it may have saved the limb. The prejudice prevailing against excision is mostly based, I believe, on deficient knowledge of good after-treatment, and, to some degree, of the technique of operation. To these two points I shall principally direct your attention. Regarding the operative procedure, I do not offer anything new. The genius of Langenbeck has presented a method, which, in spite of all new and more or less sensational modifications, is by far the best in every respect. It causes the least injury, gives the best guarantee for new formation of bone, if that can reasonably be expected, and allows of sufficient observation of the field of operation. To make the operation still more strictly subperiostal, I remove the periosteum, by means of a chisel, in all those places where ligaments or tendons are attached. In small children, in whom the epiphysis is mostly cartilaginous, free use can be made of the knife The bones are removed by means of a sharp chisel also; eventually a cross-cut is made through the periosteum of the tibia below the line of intended separation, to obviate tension and allow of free access for the chisel. In this way, also, superfluous denudation of the bone is avoided. The chisel must be sharp and thin, and form, by means of numerous small cuts, a smooth perpendicular surface on the cross-cut of the bone remaining. I always unite the periosteum cylinders by a few catgut sutures. In all cases the fibula has been excised also.

In the traumatic case, the astragalus was left untouched; in one case only its articular surface has been removed; in all the other cases it has been removed entirely. In one case, complete evidement of the os calcis was added. I need not say that antiseptic principles, with the permanent antiseptic dressing, were used in the wound-treatment. The limb is suspended by a long anterior plaster-of-Paris splint, according to Beely, into which iron rings are fastened. It reaches as far as the middle of the thigh, and keeps the knee in a somewhat flexed position. Great care must be taken during the dressing to keep the foot in such a way that it is not too much pulled forward. The assistant who holds the foot is very liable to commit this blunder. In this way the axis of the bones of the leg falls behind the intended point of the new joint, and you will see in some of my cases that I have not been able entirely to overcome this defect. In cases in which the whole astragalus has been removed, there might not result any disadvantage, because the bones of the leg are then supported by a part of the os calcis, which is lying more toward the middle line of the foot, and transfers more of the weight of the body upon the heel, In this way, I presume, the formation of pes valgus later on is avoided with more certainty. When, however, the astragalus is left, the correct relation of the axis of the leg must be strictly observed. During the wound dressing it is well to support the thigh on the calf, and to advise the person who holds the foot to fix it by gentle manipulation and slight extension, rather than to elevate the limb. After the wounds are healed, which can be achieved eventually under a few dressings—within, let us say, from six to eight weeks (in some of our cases it was four weeks; in one, the most extensive, the wound is not entirely healed after almost five months)—the patient gets a light dressing of pasteboard and starch bandage, or silicate, with quite thin wooden splints interposed. This dressing goes upward to the middle third of the thigh, and reaches down to the toes, keeping the knee slightly bent. It is split anteriorly and can be removed and reapplied by means of straps and buckles. I should advise cutting out the region of the heel to such an extent that, for reasons mentioned above, the foot can be slightly pushed backward within the dressing. I apply this dressing up to above the knee, in order to avoid rotation of the leg within the dressing. Now comes a very important stage of the after-treatment, during which, by means of active and passive movements, electricity, and bathing, the muscular action is stimulated. For this purpose, the dressing is often removed and the muscles exercised while the patient is in a lying posture, the limb being raised as much as possible. By and by, the child is made to push away a hand, which offers a slight resistance. In this way the young parts are accustomed to pressure, and after some weeks they will be so far advanced that, with the dressing—which must fit very accurately, and only allow a slight weight to be thrown upon the foot—the patient may commence to walk. The parents should be impressed with the importance of devoting all their attention to these exercises.

After several weeks more (in four of my cases about two months after the operation) the patient gets a good-fitting, double splint, which is inserted in a strong-laced shoe, and allows of a movement of about twenty degrees in the region of the ankle-joint, and reaches as high as the condyles of the tibia. Here it ends in two lateral side-pieces, which form the upper part of a pretty strong leather cylinder. The latter must be adapted very well to the upper half of the leg, as far down as the lower edge of the calf. If the patient has sufficient means, it is well to furnish every lateral splint with a mechanism by which the distance between the condyles and the sole can be increased, This can be used very well to correct abnormal pronation or supination. To improve an abnormal dislocation of the foot forward, pass an elastic ribbon across the lateral steel splints, which press slightly against the posterior circumference of the lower end of the tibia and fibula.

These apparatus will probably have to be worn for years. So far I have not deemed it advisable to remove the splint in any one of the children, though in one the operation was done almost two years ago. Four of these children run about all day, and one would hardly suppose that they had undergone such extensive operations.

I will pass around with each one of the patients a schematic sketch, illustrating the extent of the operation and principal seat of the disease. Also the specimens, as far as I deemed them worthy of preservation.

Case I.—Boy, now three and three-quarter years old, suffered from the ninth month of his age. Came under my care when not quite two years old, with scrofulous disease of the ankle-joint from osteitis of the lower end of the diaphysis of the tibia. Total excision, including the astragalus, on April 28, 1882. Extensive scrofulous cavity in lower end of tibia, which had to be removed. The scar above the new-formed tibia is now ten cm. (4 inches) long. The amount of bone removed was less, but certainly the operation was very extensive. Saw the patient for about ten days, after which time I put him under the care of my friend Dr. A. Büchler, on account of my going to Europe. Wounds healed after two months. After-treatment in the manner described. Splendid new formation of lower end of tibia and fibula. Malleoli well developed. Astragalus apparently replaced by a flat crescentic-shaped body. Slight pes valgus, for which inner side of sole had to be raised. Functional result very good. Shortening at present about two cm. ($\frac{3}{4}$ inch).

Case II.—Boy, nine years old. Came under my care four years ago with fistula above the malleolus internus, leading to scrofulous bone cavity in lower part of diaphysis, which was scraped out and healed after transient attack of inflammation in the ankle-joint. Was apparently quite well, without complaining about anything, for almost a year and a half, when slight fungoid swelling of the joint showed itself. Being absent from New York I did not see him until five months later, when the swelling had much increased, abscess had formed, and the limb was quite useless.

In October, 1882, total excision of ankle-joint, including the astragalus. Speedy recovery. Very little new formation of bone; some abnormal lateral mobility; considerable shortening of about four cm. ($1\frac{3}{5}$ inch). The femur of the affected side is also one and a half cm. ($\frac{3}{5}$ inch) shorter than that of the other. Functional result good. Boy runs about all day wearing high-heeled shoe and double steel splint. The specimen shows very beautifully the progress of the disease from the original seat of disease through the bone substance of the epiphysis to the astragalus, which shows the most destruction at a point opposite the canal which leads through the epiphysis of the tibia.

Case III.—Boy, nine years old. Had trouble with his right ankle-joint since his second year. Often repeated inflammations; later on several abscesses; transient, apparent recovery, with some pain and impaired use of limb remaining. Came under my care September 30, 1883, with abscess behind internal malleolus, which was opened, when caries of the joint was ascertained, for which excision was done on the 9th of October. From the astragalus only the articular part was removed by means of a broad, sharp chisel. Six weeks after the operation wounds completely healed. On the 2d of December shortening about three cm. ($1\frac{1}{5}$ inch). Little new formation of bone; slight lateral mobility. Malleoli narrow and axis of leg a little behind its normal insertion on the astragalus. Patient walks safely with or without brace. The excised portion of the tibia showed very deep, irregular depressions, some of which, at the line of the operation, were filled with organized tissue, while others presented a bare, carious surface.

Case IV.—Girl, six years of age. For three years slight limping and here and there pain, but foot always used until one week previous to my seeing her, when she presented thickening of lower end of tibia and inflammation of ankle-joint. September 1, 1883, complete excision, including astragalus; excellent new formation of bone and functional results. One interesting point was that seven weeks after the operation, when the patient had not walked yet, a shortening was made out of one and three-quarters cm. ($\frac{7}{10}$ inch). Three weeks later a shortening was made out of three cm. ($1\frac{1}{5}$ inch). Perhaps it would have been better to have delayed the walking exercises. The tibia is now one and a half cm. ($\frac{3}{5}$ inch) shorter than that of the opposite side. The new joint is quite firm and reliable, in spite of slight forward displacement of foot. The principal seat of the disease was a supra-epiphyseal scrofulous osteitis in the tibia.

Case V.—Boy, three years old. Commenced to suffer when nine months old. Extensive scrofulous osteitis of os calcaneum and lower end of tibia, involving the interposed joints and bones. Evidement of os calcis, complete excision of ankle-joint including the whole astragalus. In the os calcis and tibia scrofulous sequestra were found, which you see here.

Patient still under treatment, because the granulations repeatedly showed a fungoid character, and had to be scraped out. The patient commences now to walk in his starch dressing. I expect a good result ultimately, because a good new formation of bone is going on. Patient's mother died from consumption, and father is said to be consumptive. I shall present the boy a second time when he is able to walk.

Case VI.—Excision for gunshot injury. A young gentleman, eighteen years of age, tall and slender, from a healthy family, was shot by one of his friends, who was walking behind him, while the muzzle of his gun was at a short distance from the patient's heel. The load was small bird-shot. The contents of the gun entered the space between the posterior median edge of the tibia and the tendo Achillis, about two or three cm. ($\frac{3}{4}$ or $1\frac{1}{5}$ inch) above the internal malleolus, and, passing in a direction outward and forward, completely shattered the lower end of the fibula. The tibia was also broken into numerous fragments, and the tendons of the long flexors were completely torn; the tendo Achillis was partly carried away, while the tendon of the tibialis posticus was preserved. The posterior tibial nerve and artery were likewise not torn; they were lying imbedded in their bloody infiltrated sheath, within which a slight pulsation could be detected. I saw the patient about twenty-four hours after the injury, when several pieces of bone had been removed from the fibula. In spite of the extent of the injury, conservative treatment was tried by excision. Fully ten cm. (4 inches) of the tibia were removed. A large rent existed from the point of injury down to the joint within the lower end of the tibia.

The operation was done in Pine Hill, Ulster County, on August 13th, and the after-treatment for the first ten days was conducted by Dr. Laws, of this city. Then the patient was brought to New York, and I took charge of him. Extensive necrosis of soft parts, and, to some extent, of the periosteum, occurred, so that open antiseptic treatment with thorough drainage was resorted to. Complete cicatrization after five months. From that time, exercise, massage, and electricity. Patient is now able to walk, wearing a double splint with mechanism for ex-

tension, which takes part of its support on the thigh. He has been lately able to walk from one to two miles, but his foot is still weak and he uses a cane. Present shortening fully five cm. (2 inches). I ordered shoe with high heel and sole. New joint about two or three cm. ($\frac{3}{4}$ or $1\frac{1}{3}$ inch) above the normal one, at the point where the periosteum was most extensively torn. Muscular action still very weak; profuse perspiration about the foot all the time. I hope that after about a year's duration the patient will offer a very fair result.

DR. L. A. STIMSON said he had recently performed excision of the ankle-joint, and hoped soon to be able to present the patient to the Society. He also hoped that the case would show less lateral mobility than that shown by most of the cases presented by Dr. Lange, for he had preserved the malleoli in part, although removing the astragalus entire. The operation was performed after the method more recently described by Vogt, by making a longitudinal incision beginning about an inch and a half above the articular surface of the tibia and passing downward along the border of the extensor tendons for about three inches, with a short lateral incision from the lower part of this toward the tip of the external malleolus; through this incision the astragalus is easily removed and a very full view of the ankle-joint is obtained. He endeavored in his case to remove all the synovial membrane, with the preservation of the greater part of the two malleoli. It must be said, however, that in his case the disease manifested itself mainly in the synovial membrane, and only slightly in the tibia and fibula. The feature to which Dr. Lange had directed attention, namely, the displacement of the axis of the limb backward upon the foot, appeared also in his case, and he attributed it, as Dr. Lange had done, to the effect produced by pressure upon the heel, bringing the line of the weight of the body upon the foot somewhat posterior to the point where it normally falls.

DR. LANGE thought that perhaps the operation described by Dr. Stimson would be best if the disease involved the astragalus alone, but he thought it might not be possible to see all the parts involved, especially if the disease was situated pretty high up in the tibia; in such cases the longitudinal incision cannot be dispensed with. He also thought the principle to do as little injury and leave the parts in as nearly a normal condition as possible, was what especially commended Langenbeck's operation.

THE PRESIDENT remarked that he had had the opportunity to see two cases in which Busch's method of resection of the ankle was performed by making a transverse incision across the sole of the foot. Each of the different operators said that the method gave an admirable command of the parts. The result in both cases, however, was a permanent non-union of the os calcis, with considerable necrosis of the same; a result which was apprehended might occur.

The President also remarked, that last summer Neuber showed him two or three cases of necrosis of the head of the tibia, in which he had, after the removal of the diseased or dead bone, transplanted a V-shaped flap of skin into the bottom of the cavity and fastened it there by a nail. At the time they were exhibited they were doing admirably. Since then Dr. W. T. Bull had treated, in the New York Hospital, one case of tibial necrosis in the same way.

DR. F. LANGE then described a

NEW METHOD OF TREATING LARGE BONE CAVITIES IN THE LOWER END OF THE FEMUR IN ADULTS.

(See page 295.)

DR. LANGE said that he had tried the same method lately in extensive necrosis of the tibia, but without complete success. Probably for the reason which he had verified repeatedly, that in necrosis, if the operation must necessarily be performed, where there is a good deal of discharge and some infiltration of the tissues, a good deal of suppuration occurs in spite of the use of strict antiseptic precautions In the case alluded to, he was obliged to operate because the patient, a girl of perhaps five years of age, was losing weight, and gradually a somewhat hectic condition developed in spite of all efforts to build her up for the operation. The discharge was copious before and after the operation, and primary union did not take place. His operation, however, had proved somewhat beneficial, and would probably make recovery more speedy, because the inverted lateral flaps, though not fixed by primary union, had still contributed to diminish the bone cavity. He regarded the condition of the parts where primary union is expected as a very important factor. Infiltrated tissues, secreting pus somewhat freely, continue to discharge freely for some time, though the secreting surface may be removed. Apparently an irritant, lying within the tissues some distance from the wound, and being somewhat active, must first be made to disappear, either by absorption or secretion, from the free surface of the wound.

DR. A. G. GERSTER had resorted to this procedure in two cases. In one, he had to deal with a relapse of a carious affection of the lower part of the diaphysis of the femur. The patient had been operated upon fourteen or fifteen years ago, in Europe, and had been doing well ever since; but recently the disease returned, and an abscess formed, corresponding to the extensive cicatrix which occupied the inner aspect of the thigh. It was incised, and, after the disappearance of the febrile symptoms, Dr. Gerster attacked the disease itself, exposed the bone, and formed as shallow a trough as he could in the lower portion of the diaphysis of the femur. He then loosened up the skin on either side, turned the flaps into the bottom of the cavity, and fastened them in the manner mentioned. The patient had no fever, but the dressings getting soiled he removed them on the twelfth day, and found that to a considerable distance the old cicatricial substance had ulcerated under the influence of the profuse secretion which had taken place from the cavity. Nevertheless the flaps did not recede, as they do in these operations when the cavity is plugged after the old-fashioned way.

In another case Dr. Gerster performed necrotomy upon the head of the tibia, and if he had been able to obtain sufficient skin to reach to the bottom of the cavity, he thought the result would been even more satisfactory than it really was. As it was, the skin flaps were so short that he was obliged to leave uncovered a strip of bone in the median line, about one-third of an inch wide. Primary union took place as far as the cutaneous flaps reached, and there was no doubt that the recovery of the patient was very much hastened by

the procedure. He also noticed that the deep depression of the cicatrix and skin was diminishing, and, finally, is now on a level with the normal surface of the tibia, and that apparently the bottom of this depression gradually filled up with bony substance.

NECROSIS OF THE LOWER JAW, DUE TO PHOSPHORUS POISONING.

Dr. J. C. Hutchison presented the greater portion of the body of the lower jaw, which he removed from a woman forty-two years of age, who came under his observation about a year ago. She came from Frankford, Herkimer County, where she had been at work in a phosphorus factory, and from which place a number of patients had been received at the Brooklyn City Hospital. She gave the following history: Two years ago she had an ulcerated tooth on the left side of the lower jaw, which was extracted, and at the end of two weeks she returned to her work in the factory. About one year subsequently small pieces of bone began to discharge from the jaw, and she entered the hospital for the purpose of having an operation performed. Circumstances were such that it was impossible for her to remain as long as was desired before operative measures were resorted to. The operation was performed, and the bone exhibited was removed. The patient returned to her home, and Dr. Hutchison heard from her three months subsequently, when she stated that a spicula of bone had come out since her return, and he wrote to her that if she had further trouble, to let him know with reference to it. From the fact that he had not heard from the patient since, he concluded that complete recovery had ensued. He thought the specimen showed that the operation might have been deferred with advantage, if the patient could have consented, and with less loss of bone.

APHASIA FOLLOWING EXTERNAL INJURY OF THE HEAD WITHOUT WOUND OR CONTUSION OF THE SCALP.

Dr. H. B. Sands narrated a case of injury of the head, which to him seemed to be somewhat remarkable. A lady, aged forty-eight, residing in Hartford, Conn., two weeks before his visit, was thrown from a sleigh and probably struck upon her head. She was picked up in an unconscious condition, and on examination soon afterward, the attending physicians were unable to find any signs of external injury of the head, although there were marks of contusion on the neck, and also in the lumbar region. A few hours after the injury consciousness began to return, and vomiting occurred. It was also noticed that the pupil of the right eye was a little larger than that of the left, and was sluggish, although it responded to light.

The singular feature of the case was the existence of aphasia, which, though not extreme, was well marked, and presented the usual characteristics of aphasia resulting from purely pathological causes. Some change in the mental condition of the patient was noticeable, showing itself by a disposition to talk and by an unnatural degree of mirth. When Dr. Sands saw the patient she talked quite rapidly, using tolerably often a wrong word. In reading aloud about one word in every line was not the one she intended to use. She was aware of the infirmity, and became easily fatigued by mental exertion, experiencing pain on the left side of the head whenever she attempted to carry on a conversation for any length of time. The right hand appeared a little weak.

Dr. Sands was unable to recall a case exactly like the one related, and inquired what had been the experience of the members with regard to the production of aphasia from a blow upon the head. The patient's health is otherwise good, and there is no reason to suppose that any disease existed at the time of the injury. The urine has been examined, and found to be normal.

In endeavoring to account for the condition, the possibility of aphasia occurring simultaneously with the accident, as the result of some cause not traumatic, was taken into consideration. It seemed probable, however, that the lesion was due to the injury, because she presented the usual signs of concussion, and the return of consciousness was accompanied by vomiting. Moreover, examination of the heart failed to discover any valvular disease, and, as already stated, the patient's general health prior to the occurrence of the accident was known to be excellent.

Dr. Gerster mentioned a case in which aphasia took place in consequence of an apoplectic seizure during the healing of a wound made for the removal of cancerous breast, and apparently caused by embolism. The patient was sixty-two years of age. The left breast was amputated and the axillary space evacuated. Antiseptic dressings were applied, the wound was healed on the ninth day, when the patient got up and walked out into an adjoining room, lost her consciousness, and fell. She was picked up, put into bed, and when he saw her on the following morning she was unable to talk. There was hemiplegia, which disappeared during the course of the next two weeks. Deflection of the tongue and inequality of the pupils were noticed. In the course of three weeks she began to talk again, and the curious feature in the case was that she forgot the German language and spoke only her native tongue, that of Bohemia. She was unable to write, but was able to draw rough outlines of simple objects. She gradually learned certain letters, but was unable to write all letters. It was therefore a case of agraphia complicating aphasia. Recovery was gradual, and finally was so complete that she was again able to speak in German.

Her circulation was very poor, and three days before the apoplectic seizure Dr. Gerster found evidence of hypostatic congestion of the lungs. Whether this partial solidification of the lung was due to transmission of a clot from the wound into the lung, and infarction of the lung followed, from which an embolus was detached and carried into the circulation and produced the hemiplegia, he was unable to say. It seemed, however, to be in direct connection with the operation. Also whether the fall was from the apoplexy, or whether the fall produced the apoplexy, he was unable to determine positively.

Dr. Halsted remarked that the hemiplegia in Dr. Gerster's case could be explained without supposing the formation of infarction, and on the ground of the free anastomosis which had been demonstrated to exist in the lungs; so free that emboli may be carried directly through the lungs into the brain independent of the formation of an infarction.

Dr. Post referred to a case under treatment many years ago in the New York Hospital, that of a Swedish

sailor boy, who received a concussion of the brain, and while suffering from the cerebral disturbance forgot his English entirely, and was able to speak his native language only.

DR. LANGE referred to a case of disturbance in the use of language after an injury to the temporal region caused by the hoof of a horse. The man showed no deficiencies with reference to the number of words, but rather in using them intelligently. He answered questions very quickly, and words seemed to occur to him more than he needed. The case was not a recent one. A number of weeks elapsed after the injury before an operation was performed, and a large number of pieces of bone were removed, but without giving any permanent benefit. At times the patient was restless, and had to be watched and partially restrained. There were no paralytic symptoms. Finally he was discharged, uncured.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 6, 1884.

THE PRESIDENT, FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

AFTER the reading of the minutes and a report from the Section on Obstetrics, through its Secretary, Dr. Alexander Hunter, the Secretary read three communications from the Council. The first contained a report from

THE LIBRARY COMMITTEE,

in which it was stated that the volumes sent out in exchange numbered 112, while those received numbered 254, an excess of 142 volumes received.

THE PRESIDENT, in commenting on this report, remarked that it showed that if the system of exchanges was to be maintained, it would be necessary that the Academy should give more attention to the publication of its proceedings than it had done of late.

The second communication from the Council was in reference to

THE PROMPT PUBLICATION OF PAPERS,

and recommended the passage of a resolution to the effect that every paper read before the Academy should be presented to the Council, and on the approval of the latter should be immediately published at the expense of the Academy.

THE PRESIDENT suggested that those who read papers should publish only abstracts of them in the medical journals, as was the custom in Europe, reserving the full text for publication by the Academy. The object of the resolution was to insure their prompt publication, while at the same time the papers would reappear at the end of the year in the volume of *Transactions*. Still, it was not the design that there should be any compulsion in the matter, and any Fellow reading a paper could have the option of giving it to the profession through the journals, or of having it published by the Academy. The resolution was adopted.

A BENEFACTOR OF THE ACADEMY.

The third communication from the Council was in reference to a letter from Dr. Horace P. Farnham, ex-Treasurer of the Academy, in which he suggested, on account of the mortgage still remaining on the building of the Society, that those Fellows who intended to make bequests to it in their wills, should present the sums contemplated now instead, and with which he inclosed his own check for $1000. The Council recommended that, in consequence of this liberal gift, the name of Dr. Farnham should be enrolled among the Benefactors of the Academy.

On motion, the recommendation was adopted, and it was resolved that a vote of thanks be tendered Dr. Farnham, with the notification of his election as a Benefactor.

DR. GEORGE B. FOWLER then read the paper of the evening, illustrated with practical demonstrations, on

THE DETECTION OF ALBUMEN, WITH A REVIEW OF THE METHODS RECENTLY ADVANCED.

After alluding to the various kinds of albumen, he said that they were classified as native and derived, and that the native albumen which chiefly concerned the medical practitioner, was that of the blood, serum albumen. Then having spoken of some of its characteristics, he proceeded to detail a number of methods for precipitating it when present in the urine.

The first that he mentioned was by means of heat, which, he said, caused the formation of a solid clot when the quantity of albumen in solution amounted to nine per cent. Acid albumen and alkali albumen were derived forms of the substance, and neither of them was coagulable by heat. If, however, after the application of heat, a sufficient quantity of alkali in the one case, and acid in the other, were added to render the fluid neutral in its reaction, the albumen would be precipitated. He had found by experiment, that two per cent. was the smallest quantity of albumen that could be detected by heat. In experimenting with this and the other agents afterwards referred to, he had employed urine of a specific gravity of 1022, and he thought that possibly the results might be slightly different with urine of lower specific gravity than this. A point of practical importance in examining for albumen by means of heat, was to see that the urine was neither strongly acid nor strongly alkaline, and it was also always advisable to apply heat before adding acid, except for the purpose of neutralizing the fluid preparatory to making the examination.

Next he referred to the mineral acids, of which, he said, nitric acid afforded the most delicate test. By means of it, .1 per cent. of albumen could be detected. Picric acid had been suggested by Dr. Johnson, of London, and a saturated solution (about seven grains to the ounce of boiling water) was recommended for the purpose. Afterwards it was pointed out by Dr. Ralfe that the method was open to objection, on the ground that the picric acid precipitated peptones when they were present, in addition to the albumen. Dr. Johnson was inclined to doubt the existence of such a thing as peptonuria, because he had never been able to find an instance of it; but in connection with his son, a chemist, he undertook a series of experiments in regard to the matter. They found that when in any solution peptones were precipitated by picric acid, the precipitate was entirely redissolved by the application of heat. When the liquid was allowed to cool, however, the precipitate again appeared; though the addition of nitric acid cleared it up permanently. Subsequently some

one ascertained that if the urates were in excess in any urine tested by picric acid, they would be precipitated; but it was found that this precipitate also disappeared under the application of heat. The same was true as well of quinine, which, as was well known, was sometimes found in appreciable quantities in the urine of those using the drug to any considerable extent. The picric acid test was a very delicate one, detecting the presence of .1 per cent. of albumen; but it was necessary to employ great care in its use. When very minute quantities were to be detected, it was best to employ an equal bulk of the acid, as in Heller's method with nitric acid. By this means a delicate trace of albumen could sometimes be seen at the junction of the two fluids, which might escape observation if the test were used in any other way. One special advantage of the picric acid test was, that it would cause the precipitation of albumen in either a strongly acid or strongly alkaline urine.

Another class of tests in use were certain neutral salts, subsequently acidulated. One of these was the chloride of sodium (acidulated brine) test, suggested by Dr. Roberts, of Manchester. It was quite a good one, but not so delicate as the others, as the smallest amount that he (Dr. Fowler) had been able to detect with it was one per cent. Ferrocyanide of potassium, in connection with citric or acetic acid, he had found a delicate and reliable test, detecting .1 per cent. of albumen; and the same was true of tungstate of soda with an acidulated solution.

Quite recently, Dr. Oliver had introduced another test, which was altogether the most delicate that has yet been employed, viz., potassio-mercuric iodide with an acid, and it was capable of detecting .01 per cent. of albumen. The discovery of this test was not original with Dr. Oliver, but had been made by a French observer. The aim, in many of the later tests devised, had been to secure a method which could be easily practised at the bedside, and this had now been very satisfactorily accomplished by Dr. Oliver in the invention of his test-papers. There were two sets of slips of bibulous paper, one of which had been dipped in a saturated solution of citric acid, and the other in a saturated solution of potassio-mercuric iodide, and then allowed to dry. When the test was to be made, a slip of each kind was placed in a test-tube containing the urine, and as they dissolved, a precipitate would be observed to form in case albumen was present. With this potassio-mercuric iodide test, Dr. Fowler had found that almost every specimen of urine that he had examined contained at least a trace of albumen, or, at all events, some substance precisely similar in its qualities. It was a test, therefore, which could not be employed in life-insurance examinations, because it was certainly a question whether, in the great majority of cases in which he had tried the test, there was any diseased condition present. This was a matter which yet remained to be decided.

The President made a few remarks in regard to the significance of albumen when found in the urine, and said that he hoped this point would be taken into consideration in the discussion.

Dr. E. D. Hudson said that his interest in the subject was chiefly of a practical nature. While he had watched very carefully the current of medical literature in regard to the employment of new tests for albumen during the last few years, he was still strongly disposed to adhere to the old methods. The use of heat and nitric acid constituted, in his opinion, the most satisfactory tests for the busy practitioner. But even with these, there was need of the explicit instructions which Dr. Fowler had mentioned, and one very common mistake made, he thought, was the addition of nitric acid before the application of heat. He believed that it was a good rule to ascertain in all instances the chemical reaction of the urine by means of litmus paper before proceeding to test for albumen, and to add sufficient alkali or acid as the case might be, to bring the fluid to as nearly a neutral condition as possible. In cases in which there were any doubtful symptoms, it was a great mistake to dismiss the examination of urine simply because no albumen could be detected. In addition to repeated testing for albumen, repeated microscopic examinations should also be made. Heller's method often served an excellent purpose, and there was another admirable plan, which had been devised by Dr. Reuben A. Vance in 1868 or 1869. This was to take up in a pipette a little urine, and then a little acid, when, if any albumen were present, the precipitate would be seen at the junction of the two strata of fluids. Personally, he often tested simply with heat and ice-water. If, on the application of heat, a precipitate appeared which was caused by phosphates, the latter promptly disappeared when the test-tube was dipped in ice-water, the phosphates, as was well known, being redissolved by cold. In regard to some of the methods described in the paper, there seemed to him to be objections which confirmed him in the opinion that the older ones still continued the best for clinical purposes. Thus, the test-papers referred to, are too delicate, and the picric acid test required too much manipulation in order to secure freedom from errors.

Dr. Caspar Griswold remarked that there were two ways of looking at tests for albumen, one from a chemical standpoint, and the other from a clinical one. From the latter, that method was most desirable which presented the least chance of our mistaking some other precipitate for a deposit of albumen, and *vice versa*. With the picric acid test there were, apparently, a greater number of possible errors to be met with than in the case of most of the others. With regard to the potassio-mercuric iodide test, the question was, Is it desirable to find these very small quantities of albumen in the urine? If this test was a true one, a small quantity of albumen would really seem to be a normal constituent of the urine, and, at all events, albuminuria, in our modern view, was not regarded as such a serious condition as was formerly the case. On the whole, the old tests were probably sufficient for all clinical purposes. Although the application of heat might not detect such a minute quantity of albumen as some of the other tests, he thought it was the most reliable method, under ordinary circumstances, when the urine was clear. He was in the habit of pouring some of the urine to be examined into two tubes. That in one was boiled, while that in the other was not, and then the two were carefully compared; the tubes being always held against a black background. When the urine was not clear, he added one-fourth part liquor potassæ to it; after which he warmed and filtered it. Afterwards he employed Heller's cold nitric acid test. He believed, therefore, that the old

methods are really the best for the detection of albumen that was of clinical significance—if sufficient attention was given to the requisite details. However interesting a test might be in a scientific point of view, if we over-refined it to too great an extent we destroyed its practical value.

Prof. Charles A. Doremus said that he agreed fully with Dr. Griswold. Clean test-tubes and clear urine aided the medical practitioner more than very refined tests. Most of the urines submitted to examination were so turbid that it was difficult to test for albumen until they had been rendered clear. If Heller's method were employed, however, after treating the urine with an alkali, some degree of disturbance might be caused by the ebullition of a little gas, which would interfere with the delicacy of the test. In such cases, ferrocyanide of potassium and acetic acid were to be applied. This was an exceedingly delicate and satisfactory test; and metaphosphoric acid, which had not been mentioned this evening, was also a reliable one.

Dr. Munn said that he had had a very large experience in testing for albumen in connection with life-insurance examinations, but that he would speak of but a single point, and that was in reference to the very great importance of having a properly shaded light for the observation of the effect of the tests applied. Under ordinary circumstances no foreign bodies were visible in the air, but, as was well known, if a pencil of sunlight was allowed to stream into a room in a certain way, quantities of specks and particles of dust could be seen floating in it. So if the quantity of albumen was small it might entirely escape notice unless the test-tube was placed in the best possible light. The plan which he had adopted was the following: A dark window-shade was drawn down to the bottom of the window, and then held out a short distance from the sill, so as to allow the light to stream beneath it, while the test-tube was placed in front of a piece of black pasteboard fastened against the wall just below the window. By the adoption of this device he had sometimes been able to demonstrate to physicians the presence of albumen in the urine of patients in whose cases the tests made under ordinary light had previously failed to detect it.

Dr. Maxwell, another life-insurance examiner, said that when he first began to test urine for albumen he stuck to the old heat and nitric acid, and then adopted Heller's method in addition. For the last two years, however, he had principally employed picric acid, and recently he had also used sodium tungstate, combined with a small quantity of citric acid. He seldom relied on any one test, but as a rule resorted to three or four different ones in succession. Lately he had noticed in using picric acid in one instance, that a cloudiness was seen, which disappeared on the application of heat. After boiling the urine further, however, and then setting it away for twenty-four hours, the whole bulk became cloudy. Nitric acid and sodium tungstate indicated a small amount of albumen, but his first impression (from the action of the picric acid) was that it was a case of peptonuria. A specimen of this condition, however, he had not yet been able to find. He thought that the clinical significance of these later tests for albumen was not of great importance, since in every case in which any albumen at all was detected, microscopical examination would always be made for casts, and if they were found to be absent, the albumen would be regarded as of little consequence.

Dr. Fowler said, in conclusion, that the object of the paper had been to elicit such a discussion as that which had been carried on. He agreed with the last speaker, that reliance should never be placed on merely one test, and he usually resorted to the use of heat first himself. He could not agree with Dr. Griswold, however, that there was no use in going into unexplored fields in connection with this subject. A very minute quantity of albumen in the urine was sometimes of considerable clinical significance when the microscope showed the evidences of commencing renal disease. Again, it was only by such methods as those he had mentioned, that it could be ascertained whether a certain amount of albumen was not a normal constituent of the urine, since the minute quantities could not be detected at all by the old methods. In passing, he would state that peptonuria was really a condition sometimes found, and that he himself had seen undoubted examples of it—the appropriate tests showing plainly the presence of peptones.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 6, 1882.

The President R. A. Cleemann, M.D., in the Chair.

Dr. Wm. Goodell made the following

CORRECTION OF A MISSTATEMENT:

"At the last meeting of this Society, I made a misstatement with regard to that distinguished ovariotomist, Mr. Tait, which I greatly regret, and which I wish here to correct. I was misled by some remarks made by Dr. Sutton at the last meeting of the American Gynecological Society. These were so reported as to convey to my mind the impression that Billroth was the only European operator who did not refuse any case of ovarian tumor, however unpromising it was, and that Mr. Tait—to borrow Dr. Sutton's language—'does not remove many large tumors, those which weigh from sixty to sixty-five pounds, with extensive adhesions, etc.' In quoting this, by a careless slip of the pen, I changed the word 'many' into 'very,' and in addition I wholly misapprehended the purport of the above sentence. Dr. Sutton has since, in The Medical News, of February 23d, explained that he did not mean that Mr. Tait selects his cases, for he was 'not aware that this British ovariotomist refuses to remove a tumor because it is large;' but that 'Mr. Tait has the largest line of ovary and tube-cases, and the shortest line of big ovarian cysts, of any man I [Dr. Sutton] visited in Europe.' In making this correction here, I wish to repair the injustice which I unwittingly did Mr. Tait before this Society."

Dr. Goodell then exhibited an

EXTRA-OVARIAN CYST,

with the following history: The lady, æt. 28, and the mother of four children, had a miscarriage early in last October. At that time her family physician discovered the tumor. It slowly grew, but gave the lady so much inconvenience from pain and pressure that she was brought to his office late in the following December.

It was not large, but was very sensitive, and was diagnosticated to be an ovarian tumor. Both ovaries were removed early last February, and the lady recovered promptly. The peculiarities of the cyst were to him unique. The ovary lay to one side of a thick-walled cyst, and at such a distance from it that the cyst could have been removed without injury to the ovary. The latter was, however, extirpated along with the cyst, because it was diseased. Hitherto, all parovarian cysts which he had encountered were thin-walled and contained a clear fluid. But this one had thick walls and contained a turbid brown fluid. It started from the left broad ligament, and was adherent to the bladder, omentum, and abdominal wall. Another point of interest was the fact that the right ovary had doubled its size from follicular degeneration, and yet pregnancy had taken place.

Dr. Robert P. Harris suggested the possible existence of a third ovary as the starting-point of the tumor. He also thought that the presence of a third ovary might explain the persistence of the menstrual flow in some cases, after the operation of double ovariotomy.

Dr. Goodell also exhibited a

COCCYX REMOVED FOR COCCYGODYNIA.

The patient had met with a fall down stairs some years previously, and the injury was followed by a vaginal abscess of some kind. She had all the classical symptoms of a very bad coccygodynia, and had fallen into a nervous condition which bordered on insanity. Dr. Goodell had intended merely to sever the nervous attachments of the coccyx by the sweep of a tenotomy knife, but after the patient had been put under ether, the tip of the bone was found unnaturally movable, and giving distinct crepitation. The loose bone was therefore removed, and as the articulating surfaces were found rough and denuded, the whole coccyx was removed by bone-forceps. Great relief followed this operation.

Although he had seen very many cases of coccygodynia, this was the first case on which he had operated. In a very few traumatic cases he had wished to operate, but was not permitted to do so. The vast majority of these cases are, in his experience, those of nervous or neuralgic coccyx, and they get well in his hands under rest, massage, electricity, and appropriate constitutional treatment. The great difficulty, in cases of severity, is to decide between the nervous mimicry of the disease and pure traumatic coccygodynia, in which positive lesions have been sustained, and their effects have not yet passed away—as, for instance, in a sprained or a fractured coccyx, or in a rheumatic, a gouty, or an inflamed coccyx. There is yet another difficulty in the way of diagnosis, for sometimes an injury received in an hysterical woman is followed by local nervous phenomena, which will last long after the original lesion has been cured. For instance, on one occasion he had been so greatly deceived in the diagnosis between traumatic and nervous coccygodynia as to make him very cautious in resorting to the use of the knife. A highly intellectual lady, who spent her leisure in reading metaphysical works, received an injury to her coccyx by the sudden "bucking" of the horse on which she was mounted. She was at that time suffering from nervous prostration, and the blow started up very exacting coccygeal symptoms. Dr. Goodell found retroversion and a prolapse of both ovaries. These dislocations were remedied, and the patient put on a vigorous constitutional treatment; but she grew no better, and an operation was proposed and agreed to. As soon as the day and the hour were decided upon, she lost all pain in her coccyx, and has not since had a return of it. This happened about six years ago. On another occasion, he saw a very obstinate and severe case of coccygodynia, which he had been treating unsuccessfully for a long time, and which had a traumatic history, quickly disappear under an exciting family jar. In view of this experience, he believed it always safer at first to consider coccygodynia as a local expression of a general neurosis, and to treat it accordingly.

Dr. J. H. Packard asked why Dr. Goodell preferred the bone nippers to disarticulation in the first case.

Dr. A. H. Smith asked if Dr. Goodell had removed the entire coccyx. (Dr. Goodell was not sure, but thought so. There had been an abscess in connection with the injury, and the bone was dead and somewhat necrosed; he had cut off one piece with the nippers and then disarticulated the remainder.) Dr. Smith, continuing, said there had been suppurative action, probably following ankylosis. Such a condition might result from injuries received in labor, or from falling astride a chair-back or a rail. Most cases were reflex hysterical or uterine pains, as may be proved by the freedom from tenderness when the finger is pressed on the coccyx when making a vaginal examination. He has never removed one, because he has seen such poor relief from the operation in the cases that have come under his observation. Why should relief come unless all the nerves and other painful tissues be also removed? He will be glad to hear the result of the operation in the case reported by Dr. Goodell this evening.

CORRESPONDENCE.

COMPENSATION FOR EXPERT TESTIMONY IN IOWA.

To the Editor of The Medical News.

Sir: In an editorial in The Medical News of the 1st inst., entitled "Compulsory expert testimony without remuneration," you refer to Iowa as the "only State whose legislature has had the good sense to see that the true interest of the community requires that justice should be done to the medical expert."

I opine that the profession in Iowa would be happy if this were indeed true, but unfortunately it is not as relates to the present situation in this State. A later legislature has passed a later Act[1] than the one to which you refer, which provides the munificent remuneration of four dollars per diem to the physician called to give expert testimony *only*. Should he be unfortunate enough to be acquainted with any *facts* in the case, they may wring from him as many *opinions* as they like in addition, and his reward is that of the ordinary witness, and nothing more.

The absurdity of the last statement seems so great that I feel compelled to say that the Supreme Court

[1] XVI. General Assembly, 1876.

might not so decide, but the circuit judge in this circuit did, and based his decision on the ground that the law stated the expert was called *only* for expert testimony.

Yours very truly,

S. H. WASHBURN, M.D.

MASON CITY, IOWA, March 5, 1884

NEWS ITEMS.

DETROIT.

(*From our Special Correspondent.*)

THE COMMENCEMENT EXERCISES of the two medical colleges of Detroit are just finished.

THE DETROIT MEDICAL COLLEGE held its exercises in Whitney's Opera House, February 29th. Twenty-five men received the degree of M.D. In the evening, the Alumni of the College held their annual meeting. Following this was the banquet given by the Faculty and Alumni to the graduating class and their friends. All passed off in a most successful manner; peace and good will to all abounded on every hand.

THE MICHIGAN COLLEGE OF MEDICINE, on the evening of March 3d, held its commencement exercises in the same place. Twenty-seven diplomas were granted. After the exercises, the Faculty entertained their friends at a reception. At this, a harmony of feeling was verbally expressed between the three medical colleges of the State. To the outsider it was a most delightful thing to see brethren in the several medical colleges dwell together in unity. The Alumni of this college also, at a business and social meeting, elected officers for the coming year. It is stated that the matriculates of each college were about seventy-five.

THE SCHEME OF AMALGAMATING THE COLLEGES.—The efforts at the amalgamation of the two medical colleges in Detroit, which caused such a commotion last summer, have apparently subsided. Still, it is reported that the advocates of amalgamation are still at work, and hope in due time to accomplish their purpose. It is questionable whether they will succeed, as the three medical schools in the State represent at least three different modes of medical opinion—modes so different that a real union between them seems to an outsider impossible.

A STATE EXAMINING BOARD.—One of the speakers at a banquet given by one of the colleges suggested that, if a common State Examining Board be established, then every half dozen men, at such places in the State where it was convenient for them to do so, could organize a medical college, and thus secure for themselves the benefits of medical teachers' careers. Students could then be taught at or near their homes. As the classes would be small, each pupil could have the personal attention of each professor, and so to the utmost avail himself of the advantages of close contact with live teachers. In short, he thought that every doctor who so desired could then be a professor. By the State Examining Board, the work of the several bands of professors could be tested, and the really good teachers pointed out to the students.

He did not dwell upon the other effects of this scheme, only directing attention to the benefits it would confer upon the average medical practitioner in making him a professor. With a *proper examining board*, it would seem as if this scheme would be the best yet devised. Of course all these bodies would be permitted to advertise as medical colleges do, and so the powers and qualifications of every doctor in the country would become a household word with the people. It would not matter that many of these small teaching bodies had the most meagre apparatus for demonstrating the science and art of medicine. In fact, it would be very like what is now going on in a city not a thousand miles from the Ohio River. A medical friend lately related to us the results of a personal examination of this school. On paper this school has a very high standard, but as a fact our friend found that the lectures were delivered in the office of one of the professors, and that the number of students in attendance was exactly six at the time of his visit. As to dissecting-room, chemical laboratory, apparatus, diagrams, clinic rooms, etc., they were not yet developed. We have felt at liberty to direct attention to this matter, as it was openly presented by a gentleman who is a professor in one of the Detroit medical schools.

THE NEW HARPER HOSPITAL is nearly completed, at an expense of more than one hundred thousand dollars, exclusive of the ground upon which it stands. The funds for its erection and the grounds and its endowment were mainly supplied by three persons—a small farmer, a retired merchant, and a market-woman. The gifts of the two latter were made over twenty-five years since. Their gifts of city real estate have so increased in value that the trustees were enabled, from this increased value, etc., to erect the new building. It is the largest hospital building in the State of Michigan.

THE MEDICAL SOCIETIES of the city are in active operation. The Wayne County Medical Society and the Detroit Medical and Library Association meet twice a month, and the Detroit Academy of Medicine every week. The results of the work of each are apparent in the reports and papers published in the medical journals.

CINCINNATI.

(*From our Special Correspondent.*)

MEDICAL COLLEGE OF OHIO.—The commencement exercises marking the close of the sixty-fifth annual session at this institution, were celebrated Friday evening, March 7, in Music Hall. The graduating class numbered one hundred.

The exercises were opened with remarks by the Dean, Prof. W. W. Seely, M.D., who assured the friends of the College of its continued prosperity, and called attention to the advancements made in the practical departments, and the improved facilities now afforded students for both didactic and clinical instruction.

The Hon. Flamen Ball, President of the Board of Trustees, then conferred the degree upon the applicants, reminding them briefly of the importance of the profession they were entering, of the arduous and responsible duties it entailed, and of their obligation to maintain its honor.

The valedictory address was delivered by Prof. P. S. Conner. He compared the present standard of medical education with what it was twenty-five years ago, and with what it ought to be. He said that, while no one

appreciated more than he did the advantages of a thorough preliminary education, he did not think that it should be considered a prerequisite to the study of medicine. Many men who have not had the opportunity to obtain a classic education are still capable of becoming competent physicians, and may in after-life gain much of what they could not get before entering the profession. The difficulty should be not in getting into the medical school, but in getting out. A uniform lengthening of the course of study to three or four years is also to be desired; but even in this a great deal depends on the student, some being capable of acquiring in two or three years what others require a much longer time to attain. Again, there always have been and always must be, schools of different grades. It is impossible for all to attain an equal degree of perfection.

One thing that is greatly needed, he said, is the placing of our colleges upon the basis of a substantial endowment, as has so advantageously been done in New York and Philadelphia, and more recently in the Johns Hopkins University at Baltimore.

A banquet was given by the Faculty in Dexter Hall, at the close of the exercises.

The Alumni Association.—The meeting of alumni in the afternoon was largely attended.

The annual address was delivered by Dr. George T. Sutton, of Lawrenceburg, Indiana; his subject, "Changes in the Form of Diseases in the Ohio Valley."

Dr. David D. Beck, of Cincinnati, read a paper on "Color Blindness," presenting many important points in regard to principles that should be known to railroad men and water-craftsmen.

The following officers were elected:

President.—Dr. Isaac V. Gard, of Gresaville, O.

Vice-Presidents.—Drs. W. W. Dawson, of Cincinnati; Horace Coleman, of Troy, O.; W. L. Richards, of Ky.; James M. Davis, of Ind.; Joseph Aub, of Cin.

Secretary and Treasurer.—Dr. J. M. French, of Cin.

Corresponding Secretary.—Dr. A. G. Drury, of Cin.

Miami Medical College.—The commencement exercises of the twenty-fourth session of this institution took place Thursday evening, March 6.

Dr. William Clendenin, Dean, delivered the opening address, in which he invited attention to the prosperous condition of the College, even during the past year, in which so many schools have suffered a great diminution of numbers in attendance.

The degree was then conferred by the Hon. Jacob D. Cox, President of the Board of Trustees, upon the twenty-eight members of the graduating class.

The valedictory address was delivered by Prof. W. H. Taylor, who took as his subject, "The Relation of the Medical Profession to the Community." He said that the special knowledge of the physician places him under obligations to the community higher and nobler than simply his personal relations to his patrons.

At the close of the exercises, a banquet was given by the Faculty at the Burnet House.

Alumni Association.—The Alumni met Thursday afternoon. Dr. Daniel Millikan, of Hamilton, Ontario, President of the Association, delivered an address on the researches made by physicians in the various other departments of science and art, as well as in medicine.

Dr. John G. Smalley delivered the valedictory on behalf of the graduating class.

The following officers were elected:

President.—Dr. E. M. Nelson.

Vice-Presidents.—Drs. F. H. Rowe, E. S. Ricketts, W. W. Hall, and J. E. Brown.

Secretary.—Dr. W. H. Falls.

Treasurer.—Dr. G. M. Allen.

Executive Committee.—Drs. W. A. Dun, J. F. Heady, and P. Zenner.

The Cholera Bacillus Discovered in a Calcutta Water Tank.—We are informed that the discovery, by Dr. Koch and his colleagues, of cholera bacilli in a tank in the Baliaghatta suburb of Calcutta has excited much interest in Calcutta, and is there regarded as clearly a great step forward in medical science. This has occurred since the date of Dr. Koch's fifth and last report, which appeared in our columns last week.

University of the City of New York.—The forty-third annual commencement of this University was held on Tuesday evening, March 11, and the degree of M.D. was conferred on one hundred and sixty-four graduates.

The Medical College of South Carolina held its Annual Commencement on Saturday evening, March 1st. Dr. J. Ford Prioleau, the Dean of the College, read his Annual Report to the Faculty and Board of Trustees of the College, in which he stated that two years ago the Faculty instituted a graded course, extending over three sessions of attendance, available to those who wished it; the plan has been successful, and several of those who would probably have presented themselves at this time for diplomas, have postponed their graduation for another year.

The Faculty have rigidly insisted upon the period of three years being devoted to the study of the profession, inclusive of two sessions of collegiate exercises.

The degree of M.D. was conferred upon twenty candidates, and that of Phar.D. upon three candidates.

Regulation of the Practice of Medicine in Maryland; Contemplated Legislation.—A bill has been recently introduced into the Maryland Legislature, by which the State Board of Health will become, under the new *régime*, the Examining Board for the State. All graduates of reputable medical colleges, no matter as to the school to which they belong, will be entitled to practise upon presenting their diplomas and obtaining proper certificates. All persons who shall have practised medicine for ten years, upon making affidavit to that effect, shall receive a certificate entitling them to practise. Those not possessing the above qualifications shall undergo an examination at the hands of the Board, and, if the result be satisfactory, shall receive a certificate from the Board entitling them to practise. Persons undergoing examination in accordance with the Act, will be required to pay $10 to the Board. The examinations may be in writing, and shall be "of an elementary and practical character," embracing the subjects usually taught, including pathology and pathological anatomy. Itinerant physicians must pay to the sheriff $50 for each month, under the penalty of being fined not less than $50 nor more than $500, or impris-

onment from one to twelve months.—*Maryland Med. Journ.*, March 1, 1884.

DICTIONARY OF PRACTICAL SURGERY.—Messrs. Smith, Elder & Co., of London, announce a *Dictionary of Practical Surgery*, to be edited by Mr. Christopher Heath. It will be published on the plan of Quain's *Dictionary of Medicine*, which has been so favorably received by the profession.

SANITARY COUNCIL OF THE MISSISSIPPI VALLEY.—The sixth annual meeting of the Sanitary Council of the Mississippi Valley will be held in the city of Memphis, Tennessee, on Friday, March 21, 1884, instead of on Wednesday, March 19th, as previously announced.

AN AUTHOR'S RIGHTS IN HIS LECTURES.—A case has recently been pending in the Scotch law-courts, the decision in which involved the question of the rights which university professors have in their delivered lectures. Judgment has been given, and the Court holds that professors are fully entitled to the benefits of the Copyright Acts; and that the mere delivery of the lectures to a class, each member of which has paid a fee to listen to them, does not in any way affect the lecturer's right of property in them, nor does it in any way give another person the right to publish or reproduce the lectures. In the present case, the action has been raised by the Professor of Moral Philosophy in the University of Glasgow against a local bookseller, who offered for sale a book entitled *An Aid to the Study of Moral Philosophy*, which was wholly or in substance a reproduction, more or less correct, of the lectures delivered by Professor Caird to his class in moral philosophy. With the view of still further protecting Professor Caird's interests, the judge gave him the full benefit of the Copyright Act, and not only bound over the defendant to stop the publication of the book in dispute, but ordered him to deliver up all the copies remaining in his hands, or within his control, in order that they might be destroyed. This decision is an authoritative statement upon a point of some importance, and about which there has heretofore existed some difference of opinion.—*British Medical Journal*, March 1, 1884.

EDINBURGH UNIVERSITY TERCENTENARY.—The following programme has been issued of the ceremonies by which the close of the Three Hundredth Session of the Edinburgh University will be celebrated. The festival is to extend over Wednesday, Thursday, and Friday, 16th, 17th, and 18th of April. It is proposed that on Tuesday evening a grand reception shall be given by the Magistrates and Council in the Museum of Science and Art. On Wednesday, the new College Buildings will be formally opened, and it is understood that the Senatus are endeavoring to get a member of the Royal family to undertake this duty. The proceedings on this day will begin with a reception by the Senatus in their hall, then there will be a religious service in St. Giles's, and afterwards the opening of the College Buildings will take place. On Thursday, or on one or other of the specified days, there will be a graduation ceremonial, at which a number of honorary degrees will be conferred. On Thursday evening there will be a grand banquet, probably in the Corn Exchange; on Friday afternoon a students' concert, and on the evening of that day a ball. It is not unlikely that in connection with the celebrations an illumination of the principal streets of the city will be recommended by the Magistrates and Council, though this has not been finally determined.—*Medical Times and Gazette*, Feb. 23, 1884.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending March 1, 1884, indicate that inflammation of the bowels has increased, that influenza has considerably decreased, and that pneumonia, intermittent fever, bronchitis, rheumatism, diarrhœa, remittent fever, and inflammation of the kidney, have decreased in area of prevalence.

Compared with the average for the month of February in the six years, 1877 to 1882, neuralgia was more prevalent, and pneumonia, diphtheria, bronchitis, remittent fever, typho-malarial fever, and rheumatism were less prevalent in February, 1884.

Including reports by regular observers and others, diphtheria was reported present during the week ending March 1st, and since, at ten places, scarlet fever at twenty-two places, and measles at seven places. Four cases of smallpox were reported at Bath, February 29th.

OBITUARY RECORD.—DR. MENDEZ ALVARO. On the 9th of December, 1883, a large number of physicians of Madrid and the provinces celebrated the fiftieth scientific anniversary of Dr. Mendez Alvaro; ten days later he died. Dean and Founder of the Spanish School of Hygiene, President of the Royal Academy of Medicine, and Director of *El Siglo Médico*, Dr. Alvaro was the author and editor of numerous works, the first, a manual on auscultation, having appeared in 1835. The professional and scientific interests of medicine in Spain had always in him a warm advocate and supporter. He was a distinguished savant, a learned writer, and a good man.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 4 TO MARCH 10, 1884.

PERIN, GLOVER, *Lieutenant Colonel and Surgeon.*—Medical Director, Department of Dakota, leave of absence extended twenty days.—*S. O. 23, Headquarters Division of the Missouri*, March 5, 1884.

BILL, J. H., *Major and Surgeon.*—Granted leave of absence for one month.—*Par. 1, S. O. 20, Headquarters Department of the Platte*, March 3, 1884.

BACHE, DALLAS, *Major and Surgeon.*—Leave of absence extended seven days.—*Par. 1, S. O. 43, Headquarters Department of the East*, March 5, 1884.

STEPHENSON, WILLIAM, *First Lieutenant and Assistant Surgeon.*—Ordered to Fort Niobrara, Nebraska, for temporary duty, on completion of which to return to his station, Fort Omaha, Nebraska.—*Par. 4, S. O. 20, Headquarters Department of the Platte*, March 3, 1884.

FISHER, WALTER W. R. and PALHEMUS, ADRIAN S., *First Lieutenants and Assistant Surgeons.*—Assigned to duty in the Department of California.

STEPHENSON, WILLIAM, BORDEN, WILLIAM C., and CHAPIN, ALONZO R., *First Lieutenants and Assistant Surgeons.*—Assigned to duty in Department of the Platte.

ROBERTSON, REUBEN L., and EDIE, GUY L., *First Lieutenants and Assistant Surgeons.*—Assigned to duty in Department of Texas.

CROSBY, WILLIAM D., *First Lieutenant and Assistant Surgeon.*—Assigned to duty in Department of Arizona.

GAUDY, CHARLES M, *First Lieutenant and Assistant Surgeon.*—Assigned to duty in Department of the East.

PILCHER, JAMES E., *First Lieutenant and Assistant Surgeon.*—Assigned to duty in Department of Dakota.—*Par. 4, S. O. 55, A. G. O.*, March 6, 1884.

ORIGINAL LECTURES.

ON THE TREATMENT OF TYPHOID FEVER.[1]

A Clinical Lecture.

BY PROF. DUJARDIN-BEAUMETZ,
OF PARIS.

GENTLEMEN: There is, perhaps, no question in therapeutics which has caused so much discussion as the treatment of typhoid fever, and, if I were to follow out all the lines of inquiry which this subject has opened, I should require, not one lecture, but the entire course. I shall, then, be as brief as possible on points of theory, and dwell rather on practical conclusions. Whether you practise in the country or in the city, you will continually meet with cases of abdominal typhus. Last year (1882) you saw our wards filled with the victims of one of the most severe epidemics that have ever afflicted the population of Paris, and the hall of the Academy of Medicine still rings with the passionate discussions which were raised by the various questions pertaining to this great problem of hygiene and therapeutics.

Etiology, as I have often told you, has an important bearing on the treatment of disease; you recognize, then, the propriety of considering first the causes of typhoid fever; for, if they were absolutely known to us, we should be able henceforth to establish on a scientific basis the prophylactic treatment of this disease. This particular point in the study of dothinenteritis has been especially investigated during the last few years, and we shall have here to discuss the contagiousness and spontaneity of this affection. According to some authorities, typhoid fever is always the result of a particular contagion; according to others, it comes from a miasmatic poison. You cannot be ignorant, Gentlemen, of the difference which separates *contagium* from *miasm*, a distinction well established by Liebermeister; *contagium*, coming from specific, morbific agents, which always take their origin and undergo development in a diseased organism; *miasm*, on the contrary, being generated outside of, and independent of, an infected organism. To make more orderly and clear the exposition of this difficult subject, I shall commence with points which are best established and least open to dispute; then I shall take up those which are most amenable to discussion.

To-day, everybody is agreed in admitting the contagiousness of typhoid fever. It is especially in our rural districts that this contagion is observed in its worst form, and every year the reports made to the Academy of Medicine on the prevalent epidemics contain facts establishing the contagiousness of this disease. We can go even further, and declare that to-day the active principle of this contagium has been determined. This principle is found exclusively in the stools of typhoid patients, and it needs but a very minute quantity of this pernicious element in potable water to communicate ileo-typhus to all who drink of it. We possess, to-day, a considerable number of observations which establish this fact on an undisputable basis. The latest and most accurate is, assuredly, the observation published by Dionis des Carrieres, concerning the epidemic which lately devastated the city of Auxerre, where one of the springs which supply the city was proved to have been polluted by the dejections of a woman sick with typhoid fever. The entire population which derived its drinking water from this source was infected, and there were few that did not suffer more or less; those parts of the city, however, which did not make use of this water had entire immunity from the epidemic.

The attempt has been made by experiments on animals to elucidate this subject, but these have given uncertain results, and to the positive experiments of Birch-Hirschfeld, of Letzerich, and of Tizzoni, we must oppose the negative results of Robert Bahrd and Motschutkoffsky; moreover, the basic premise of these researches is under dispute, for it is not proved that the lower animals can contract typhoid fever.

But it is not enough to know that it is by the dejections that typhoid fever is communicated. Pathologists, guided by the theories of Pasteur, have sought in the dejections, and even in the tissues of victims of the disease, the microbe which contains the contagious principle. Unfortunately, we have not here any positive information; not because micro-organisms are not exceedingly abundant in the stools of typhoid patients, but because amid this abundance it is difficult to tell exactly which one of these microbes is the essential element of dothinenteritis. It is generally known that Recklinghausen has found micrococci, Eberth rod-like forms, and Klebs has described, under the name of *bacillus typhosus*, certain elongated filaments; but despite these researches, and those of Koch, of Meyer, of Friedlander, of Maragliano, of Almquist, we are still ignorant of the real microbe of typhus abdominalis. In a word, the parasitic theory of typhoid fever is almost certain, but it has not yet been scientifically demonstrated in a rigorous manner.

As opposed to this doctrine of contagiousness, we must allude to that of spontaneity. Struck by the fact that typhoid fever exists endemically in all places where are accumulated a great number of individuals—as in our great city; moved also by the appearance of certain epidemics apart from all known contagion; comparing, moreover, the typhus of armies with the abdominal typhus of great cities, certain authorities have maintained that typhoid fever may be produced spontaneously under the influence of bad hygienic conditions; and the cause has been by turns assigned to fecal matters, overcrowding, spoiled alimentary substances, and even to certain bad geological conditions of the soil. Let us rapidly examine each of these points.

Murchison has been the chief defender of the first of these causes, and he has labored to show that fecal

[1] Translated from advance sheets by E. P. Hurd, M.D., of Newburyport, Massachusetts.

matters may spontaneously develop a miasmatic principle which, entering the human system, may engender there ileo-typhus. Between him and Budd quite a lively discussion arose; Budd maintaining that fecal matters were dangerous only when they were fouled by the dejections of a typhoid patient.

These are the two so-called fecal theories of typhoid fever. It was, however, a mistake to confound these theories under one name, for if Budd's view be correct, Murchison's cannot be; for it is not yet rigorously demonstrated that fecal matters may spontaneously generate the typhoid poison. This fecal theory has served as argument to the adversaries and to the partisans of the exclusive sewerage doctrine, which condemns the fixed privy-vaults and the separate systems of removal, and insists that all night-soil shall be consigned to the public sewers, which shall be constantly flushed with running water—the latter, with its excrementitious products, being finally subjected to the filtering and purifiying action of the soil. This whole matter of sewerage is not yet settled; yet despite the opposition in certain quarters, the majority of hygienists and civil engineers are of opinion that those cities which have the best system of sewerage are the best protected from typhoid epidemics.

I do not wish to enter into the details of this discussion, which would draw us away from our subject. I shall only call your attention to the action of oxygen on all putrescent materials floating in sewers—an action which Fauvel has clearly shown in making it plain that this oxidation is a veritable combustion, which rapidly destroys the infectious element in night-soil; and we see in this an explanation of the fact that the South and East, despite their deplorable hygienic conditions, manage (by free exposure of their filth to atmospheric air) to keep tolerably free from epidemics. Although Rochard has affirmed that it would be easy to develop typhoid fever by the simple fact of massing people together in close quarters and under bad hygienic conditions, I believe that this overcrowding is a more powerful factor of typhus exanthematicus than of abdominal typhus. I make the same reserves in reference to the subject of alimentation as the determining cause of ileo-typhus. Wernich, comparing the bacillus of typhoid fever with that of putrefaction, has ably maintained that the use of spoiled meats is a cause of typhoid fever. It has also been asserted that the use of water polluted by organic detritus, and that even milk contaminated by water of bad quality, might also be a cause. I consider all these circumstances as adjuvants; but no one of them alone seems to me sufficient as a determining cause of this disease. It is the same with geological conditions. The doctrine which is supported by Pettenkoffer and Buhl, attributes epidemics of typhoid fever to a lowering of the stratum of subterranean water. Observations have in fact demonstrated that if this theory is conformable to what has been observed at Munich, it is not applicable to epidemics in other parts of Europe.

As you see, Gentlemen, it is not yet proved that any of the causes just alleged may spontaneously give rise to typhoid fever; and I am ready, for my part, to give my adhesion to the parasitic theory of this affection. It is true that this doctrine of *contagium vivum* denies all spontaneity, but it enables us to explain—thanks to the theory of vaccination (or, if you prefer so to put it, of preservation by attenuated virus), it enables us, I say, to explain the immunity of typhoid patients from all future attacks of the disease. It enables us, also, to understand the comparative immunity of individuals who have long lived in Paris as contrasted with those who have lived there but a short time; the first having acquired, by long exposure to the virus, constitutional modifications which prove a relative protection.

It enables us, moreover, to hypothesize atmospheric or telluric conditions, favoring in some degree the culture of germs of the typhoid contagion, without being compelled quite to indorse the explanation which Ernest Besnier has given of the march in accordance with seasons of the dothinenteric epidemic. But, on the other hand, this theory of living contagium leaves in the shade many points in this interesting part of etiology, and in particular the epidemic character of this affection, and the special features which distinguish each epidemic—circumstances which render so difficult the application of statistics to the study of the therapeutics of typhoid fever. Nevertheless, despite these reserves, I adopt the theory of contagium rather than that of miasm.

From the facts which I have just set forth, flow very important hygienic applications, some concerning public hygiene, into the consideration of which I shall not enter, others concerning private hygiene, and which in their totality constitute the hygienic and the prophylactic treatment of typhoid fever. As it seems to be absolutely proved that the typhoid virus is found in the fecal matters of persons suffering from the disease, and that water polluted by these dejections is the most powerful factor of the contagion, it follows that it is a duty thoroughly to disinfect these alvine dejections, and the objects which they have polluted. It follows, also, that one should have a careful surveillance of potable water, and, if not certain of its purity, such water should be boiled before being used, or some of the table waters should be employed, such as Apollinaris. Moreover, I refer you in this connection to the instructions issued by the Council of Hygiene, of which I am a member, concerning the measures to be taken to stay the progress of the epidemic of typhoid which raged over this city in 1882.

So much for the prophylactic treatment. The hygienic treatment is of capital importance, and the more you see of this disease the more you will appreciate its importance. Under this head I shall examine, successively, the dietary regimen, the measures to promote cleanliness, and the care of the sick-room.

For the severe and cruel regimen of Broussais, who opposed feeding fever patients, we now substitute the administration of nourishment as a necessary part of the treatment, and no disease so markedly shows the advantages of generous alimentation. You must, then, feed your typhoid patients; but, remembering the disorders of which the digestive tube is the seat, you should exercise great care in the choice of nourishment, which should be chiefly liquid; and every substance should be prohibited which might become a source of irritation in the alimentary canal. Give your patients, then, milk, broths, well-strained gruels, and stimulating drinks, such as wines and vinous lemonades. These beverages constitute the only drinks permissible. I make exception of plain lemonade, a beverage which, without possessing any marked anti-febrile properties, is always refreshing to fever patients. When there exist gastric disturbances, and you wish to support the patient, you may give iced

champagne. It is generally a good thing to add ice to the ordinary drinks of the patient.

But the time when you should redouble your watchfulness is when you come to the convalescing period of the disease. During convalescence, the patient either has a ravenous appetite or he has no appetite at all. Where appetite exists and is imperious, you will have to exercise rigorous care in prohibiting too free indulgence in all kinds of food. For my part, I have three or four times in my life seen convalescent patients die from excessive eating. I remember well a patient in the Hôtel Dieu, where I was attending, who was convalescing from a very severe attack. He went out of the hospital, and the first thing he did was to help himself to a hearty meal. The next day he came back to the hospital with all the symptoms of peritonitis, from which he died. The autopsy revealed an intestinal perforation. You should have such facts always in mind when you direct the dietary of fever patients during their convalescence, and although the instinct for food at such times is a natural one, the utmost judgment is required in its gratification.

In other cases, there are anorexia, vomiting, and dyspepsia; symptoms which, as our colleague, Anatole Chauffert, has well shown in his thesis on the gastric complications of typhoid fever, depend on the alterations which the gastric mucous membrane has undergone from the typhoid process. Here we must apply all the measures which are addressed to the treatment of ulcerous gastritis—a diet of pure milk, which gives rest to the enfeebled stomach, milk punch with meat powder; this is an excellent way of giving this highly nutritive preparation. It may, finally, be necessary to resort to lavage of the stomach and to forced feeding.
